The effect of pressure on conductivity can be treated independently of temperature, so that one can write:

Lithosphere, Continental: Thermal Structure, Table 3 Constants for calculating the thermal conductivity of different rock types. (From Clauser and Huenges (1995))

Rock type	T range (°C)	A	B
Metamorphic rocks	0–1200	0.75	705
Felsic rocks	0–1400	0.64	807
Mafic rocks	50–1100	1.18	474
Ultramafic rocks	20–1400	0.73	1293

Lithosphere, Continental: Thermal Structure, Table 4 Pressure dependence of lattice conductivity

Material	$\beta^a \times 10^{-2} \text{ GPa}^{-1}$	Reference
Mafic granulites (Finland)	2.4 ± 0.8	Kukkonen et al. (1999)
Olivine	3.2	Xu et al. (2004)

^aCoefficient in Eq. 15 for thermal conductivity

$$\lambda(T, P) = \lambda_o(T)(1 + \beta P) \quad (15)$$

where β is a constant coefficient (Table 4). The effect of pressure increases conductivity by about 20% between the surface and 200 km.

For olivine, several independent laboratory measurements suggest that:

$$\lambda_R = 0.368 \times 10^{-9} T^3 \quad (16)$$

This equation leads to $0.13 < \lambda_R < 1.8 \text{ W m}^{-1} \text{ K}^{-1}$ for $700 < T < 1700 \text{ K}$. It is only valid in a single crystal if the mean free path of photons is independent of temperature. For mantle rocks, one must account for scattering and for the effect of interfaces in a mineral assemblage. Such complications led Marton et al. (2005) to use a constant radiative conductivity component $\lambda_R = 1 \text{ W m}^{-1} \text{ K}^{-1}$ for temperatures higher than 700 K.

Lithosphere, Mechanical Properties

Evgueni Burov
(Deceased)

Synonyms

Geosphere

Definition

Lithosphere (mechanical). This is the rigid (“litho” = stone) outer layer of the Earth that remains mechanically strong over geological time spans. *Mechanical lithosphere* includes rigid layers of crust and outermost mantle capable to maintain high differential tectonic stresses, from 10 MPa to 1 GPa. *Mechanical lithosphere* is 1.5–2 times thinner than “seismic,” “thermal,” or “chemical” lithosphere.

Mechanical properties of the lithosphere. This term refers to the *integrated strength* of lithospheric plates, their *rheological structure* and parameters, and mechanical behavior in response to various tectonic loads.

Introduction

Mechanical properties of the lithosphere are of primary importance for local and global geodynamics. In particular, compared to the convective mantle, high long-term mechanical strength makes the lithosphere a unique stress/strain guiding and accumulating envelope with lasting mechanical memory. High strength prohibits internal *heat advection*, so *thermal conduction* is main heat transfer mechanism in the lithosphere, in contrast to the convective mantle. High strength also stabilizes vertical lithological structure of lithosphere making it a *stagnant layer*. In contrast to viscous mantle, long-term *rheology* of the lithosphere is strongly influenced not only by its *ductile* but equally *elastic* and *brittle* properties. It is probably the nonviscous properties of the lithosphere that shape it in the characteristic *plate tectonics* patterns.

The term *lithosphere* has been introduced in the second half of the nineteenth century, while the notion of *mechanical lithosphere* appeared in early twentieth century, in conjunction with that of *seismic lithosphere* (see ► “[Earth’s Structure, Global](#)”), after formulation of the *continental drift theory* by Wegener and first interpretations of *regional isostasy* by J. Barrell and Vening-Meinesz (Watts 2001; see entry ► “[Isostasy](#)”). The fact that the lithosphere has finite measurable strength has been demonstrated from observations and models of *regional isostatic compensation* of large topographic loads. Before that, the lithosphere was considered either as a very strong solid layer (*Pratt’s model*) or, in turn, a weak fractured layer (*Airy’s model*). *Postglacial rebound studies* of early twentieth century have contributed to the definition of the *mechanical lithosphere* as the uppermost layer of the solid earth characterized by slow *viscoelastic relaxation*, in contrast to the underlying, relatively low-viscosity asthenosphere. The long-term mechanical base of the lithosphere, h_m , is limited by the depth to isotherm 500–600 °C in oceans and 700–800 °C in continents, compared to almost twice as deep 1,330 °C isotherm delimiting the thermal lithosphere (see entries ► “[Lithosphere, Oceanic: Thermal Structure](#)” and ► “[Lithosphere, Continental: Thermal Structure](#)”). As suggested on the basis of recent mantle–lithosphere interaction models (e.g., Schmeling et al. 2008), it is the elastic and plastic properties of the lithosphere that essentially determine the geometry of lithospheric plates and the mechanisms of formation of constructive, destructive, and transform plate boundaries at global scale. At smaller scale, *mechanical properties* of the lithosphere control formation and evolution of major geological structures such as rifts, passive margins, foreland basins, mountain ranges,

plateau or strike-slip faults. They also control short-term processes such as seismicity (Watts and Burov 2003).

Mechanical Properties at Different Timescales

Mechanical properties of the lithosphere are timescale dependent (e.g., Watts 2001). At seismic timescales (<0.5 h), the lithosphere behaves as an elastic or brittle-elastic layer of a thickness largely exceeding h_m . At *post-seismic timescales* (from days to years), the uppermost crust relaxes a part of seismically induced stress evoking some rather poorly understood short-timescale viscoelastic properties. At *postglacial rebound* timescales ($\sim$ several 1,000 year), lithosphere remains largely elastic, with thickness of the elastic domain almost as important as its *seismic thickness*. At geodynamic timescales (>1 Myr), the thickness of the *elastic core* is reduced to values smaller than h_m , and the stresses are slowly relaxed at timescales on the order of several Myr. The long-term properties of the lithosphere were first assessed from geodynamic-scale observations, first of all, *regional isostasy*. According to these data, the lithosphere exhibits a large spectrum of long-term behavior from quasi-elastic to brittle and viscous. Observation of crustal and lithosphere scale faults and *distributed seismicity* shows that some domains within the lithosphere deform in brittle-plastic regime over long time spans, while relaxation of deformation below, for example, oceanic volcanic islands, points to long-term viscoelastic strength. However, the long-term properties of the lithosphere are more generally studied indirectly using extrapolations from *rock mechanics data*.

Sources of Information on the Mechanical Properties of the Lithosphere

Flexural studies and *experimental rock mechanics data* are major sources of quantitative information on long-term behavior and strength of the lithosphere. In structured *viscous-elastic-plastic* media, all rheological properties are interrelated, and various time- and scale-dependent factors may cause variations in the effective elastic, brittle, and ductile deformation. Consequently, observations of long-term deformation are of primary importance for assessment of the effective mechanical properties of the lithosphere. These and other sources of information are summarized below:

1. Observations of long-term ($t > 1,000$ year) lithosphere response to tectonic loading, in the order of importance:
 - Observations of *regional isostatic compensation: gravity-flexural studies* providing estimates for the *equivalent elastic thickness* of the lithosphere, T_e
 - Vertical motions due to *postglacial rebound, lake, and volcanic island* loading
 - Observations of *lithosphere folding* (*folding wavelength* is a function of plate strength)
 - Field observations of ductile and brittle deformation in the outcrops
 - Interpretations of *deformational microstructures* and *paleo-stresses*
 - *Seismic tomography* (e.g., evidence for more or less strong slabs at depth)
 - *Borehole* stress measurements
2. Intermediate timescale observations ($t > 3\text{--}10$ year):
 - *Slow-rate rock mechanics experiments* (strain rates 10^{-9} to 10^{-4} s $^{-1}$, for ductile properties)
 - Geodetic (GPS-INSAR) data over >5 year time spans (strains, viscoelastic properties)
 - *Inter-seismic deformation; slow earthquake data*
3. Observations of deformation in response to short-term loading ($t < 1$ year):
 - Short-term *rock mechanics experiments* (elastic and brittle properties)
 - Distribution of intraplate seismicity (brittle properties)
 - Tidal deformation (viscoelastic properties)
 - Post-seismic relaxation (viscoelastic properties)
 - Geodetic (GPS-INSAR) data (strains, viscoelastic properties)
 - Attenuation of S waves (proxy to low-viscosity zones)
 - Magnetotelluric sounding (reduced electrical resistivity is proxy to low-viscosity zones)
4. Physical considerations and self-consistent thermo-mechanical models:
 - Estimates of the minimal *integrated strength* of the lithosphere required for lifetime stability of geological structures, *subduction* or transmission of tectonic stresses, and forces over large spatial scales, including horizontal pressure gradients caused by lateral variations in lithospheric density structure and topography (*gravity potential energy* theory). For example, lithosphere must be strong enough to transmit *ridge push* and *slab pull* forces on the order of $10^{11}\text{--}10^{13}$ N per unit length.
 - Lithosphere scale *numerical thermo-mechanical models* of tectonic processes integrating multidisciplinary data, which allows for testing the validity of data and hypotheses on lithosphere rheology.

Observations of long-term deformation provide key parameters such as the *integrated strength* of the lithosphere. These parameters are needed to constrain *rock mechanics data* obtained at laboratory conditions, because they are too far from geological conditions: short timescales ($t < 5$ years), small spatial scales ($l \sim 0.1$ m), high strain rates ($\dot{\epsilon} > 10^{-9}$ s $^{-1}$), small strains ($\epsilon < 10$), high temperatures, simple deformation, largely mono-phase samples. *Rock*

mechanics data allow only for assessment of general form of rheology laws, their sensitivities, and relative strengths of different kinds of rocks. Their extrapolation to geodynamic scales ($t > 10^6$ years, $l \sim 1,000$ km, $\dot{\epsilon} < 10^{-14} \text{ s}^{-1}$, $\epsilon > 100$, cold temperatures, aggregate rocks) needs re-parameterization and validation using real-scale observations and models.

Interpretation of short-term data (seismic, satellite geodesy, INSAR) is not straightforward. In particular, interpretation of *intraplate seismicity* (see entry ► “[Seismicity, Intraplate](#)”) and *post-seismic relaxation* data is questioned due to the lack of evidence that mechanisms of this short-term deformation can be physically linked to those of long-term deformation.

Observations of Flexural Behavior and Effective Long-Term Strength of the Lithosphere

Observations of *regional isostatic compensation* (e.g., Watts 2001; see entry ► “[Isostasy](#)”) have shown that the lithosphere has substantial long-term *elastic rigidity* that allows for transferring and maintaining intraplate stress levels (10 MPa–1 GPa) over geodynamic time spans (>several Myrs). Studies of gravity anomalies observed over mountain ranges and subduction zones have demonstrated that lithospheric plates bend like *thin elastic plates* of finite stiffness in response to tectonic, topography, and sedimentary loads. With improvement of geophysical measurement techniques during the second half of twentieth century, multiple studies (specifically, forward *flexural models*) have produced robust estimates of *flexural rigidity*, D , and *equivalent elastic thickness*, T_e , of lithospheric plates. These data arguably present a major source of information on the long-term *mechanical properties* of lithosphere. *Flexural studies* reveal strong variations of lithosphere strength, from near zero at ocean ridges to 100–150 km thick quasi-elastic cores detected within old and cold cratons (Burov and Diamant 1995; Kirby and Swain

2009). In *flexural models* of *regional isostatic compensation* (Watts 2001), D is varied until the model-predicted basement or *Moho topography* provides optimal fit to observations. *Gravity data* (see entry ► “[Gravity Anomalies, Interpretation](#)”) are used when basement topography is hidden (e.g., by sediments) or not representative of flexure (e.g., modified by erosion). The most robust *gravity models* are *forward models*. *Inverse models* are widespread due to the ability to cover large zones, but their results are more sensible to errors and should be cross-checked with *forward models*. For example, if not properly formulated, *gravity admittance* techniques may generate spurious results in continents (e.g., Kirby and Swain 2009).

D provides a direct measure for the *integrated long-term strength* of the lithosphere and is linked to the *equivalent elastic thickness* of the lithosphere, $T_e: D = ET_e^3(12(1 - \nu^2))^{-1}$, where E and ν are Young’s modulus and Poisson’s ratio, respectively. *Plate bending or flexure* is characterized by its vertical deflection, $w(x)$ and local radius of curvature, $R_x(x)$ or curvature, $K(x) = -R_x^{-1} = \partial^2 w / \partial x^2$ (Fig. 1). The flexural equation, when expressed using *bending moment* $M_x(x)$ is rheology independent and is valid for all, elastic and inelastic plates:

$$\frac{\partial^2}{\partial x^2} \left(\overbrace{\frac{ET_e^3}{12(1 - \nu^2)} \frac{\partial^2 w(x)}{\partial x^2}}^{M_x(x)} \right) + \frac{\partial}{\partial x} \left(F_x \frac{\partial w(x)}{\partial x} \right) + \Delta \rho g w(x) = \rho_c g h(x) + p(x) \quad (1)$$

where F_x is horizontal *fiber force*, $\Delta \rho$ is the density contrast between surface and subsurface material (i.e., between mantle density ρ_m and topography/sediment/water density ρ_c), $h(x)$ is topography elevation, and $p(x)$ is additional surface or subsurface load. The elasticity is used just as simplest

Lithosphere, Mechanical Properties, Fig. 1 Classical flexural model of oceanic lithosphere (left). Right: brittle-elastic-ductile yield stress envelope (YSE) and interpretation of the equivalent elastic thickness T_e of the lithosphere. $\epsilon_{xx}(z)$ is flexural strain, $\sigma_{xx}(z)$ is flexural stress,

$K(x)$ is local plate curvature, $\Delta\sigma$ is differential stress, $Z_n(x)$ is neutral plane, and T_s is brittle seismogenic layer. $w(x)$ is vertical plate deflection. V_0 and M_0 are boundary cutting force and flexural moment, respectively

rheological interpretation of bending strength: elastic bending stress is linear function of curvature and depth: $\sigma_{xx}(x, z) \approx (0.5T_e - z)EK(1 - \nu^2)$. T_e is thus effective parameter and should not be automatically related to any real layer within the lithosphere. For inelastic plates, T_e and D have a sense of “condensed” plate strength and are direct proxies for the long-term *integrated strength*, B , of the lithosphere (Watts 2001). For example, for a single-layer oceanic plate ($T_e = T_{e_ocean}$, Fig. 1):

$$B = \int_0^{h_m} \sigma^f(x, z, t, \dot{\epsilon}) dz$$

$$\text{while } T_{e_ocean} = \left(12 \left(\frac{\partial \sigma_{xx}^f}{\partial y} \right)^{-1} \left(\int_0^{h_m} \overbrace{\sigma_{xx}^f(z - Z_n) dz}^{M_x(x)} \right) \right)^{\frac{1}{3}};$$

$$T_{e_ocean} < h_m$$

(2)

where σ_{xx}^f is brittle-elastic-ductile bending stress (Burov and Diamant 1995); T_e is usually much smaller than h_m . M_x and, hence, D can be obtained from depth integration of σ_{xx}^f . D and T_e may spatially vary due to their dependence on local bending that leads to localized plate weakening (called *plastic or ductile hinging*) in the areas of utmost flexure, for example, near *subduction zones* or below mountains and islands.

Rheological Properties of Lithosphere According to Rock Mechanics Data

The long-term mechanical behavior of rocks is represented by *extended Maxwell solid*, in which total strain increment equals a sum of elastic, viscous (ductile), and plastic (brittle) increments while the elastic, viscous, and plastic stresses are mutually equal. The weakest rheological term thus defines the effective behavior of this solid. Goetze and Evans (1979) used *Maxwell solid* and rock mechanics data to introduce the *yield stress envelope* (YSE) of the lithosphere (Figs 1 and 2). This approach consists in predicting, for a representative *background strain rate* and depth–pressure–temperature profile, the maximal *yield strength* $\Delta\sigma_{\max}(z)$ as function of depth, z . If elastic *differential stress* estimate $\Delta\sigma^e(z) < \Delta\sigma_{\max}(z)$, the deformation is elastic and *differential stress* $\Delta\sigma(z) = \Delta\sigma^e(z)$. If $\Delta\sigma^e(z) \geq \Delta\sigma_{\max}(z)$, then $\Delta\sigma(z) = \Delta\sigma_{\max}(z)$ and the deformation is brittle or ductile depending on z .

Elastic Properties

The *elastic behavior* is described by linear Hooke’s law:

$$\sigma_{ij} = \lambda \epsilon_{ii} \delta_{ij} + 2G \epsilon_{ij} \quad (3)$$

where λ and G are Lamé’s constants. Repeating indexes mean summation, δ is Kronecker’s operator. For most rocks $\lambda \approx G = 30$ GPa (Turcotte and Schubert 2002).

Lithosphere, Mechanical Properties, Fig. 2 Commonly inferred (brittle) rheological *yield stress envelopes* (YSEs) as function of *thermotectonic age* for oceans and continents. In mantle, maximal strength can be limited by *Peierls* or *GBS* law instead of

Byerlee’s law. For continents, variations in crustal composition and fluid content result in various *Jelly Sandwich*, *Jelly Sandwich*, and more rare *Crème Brûlée*. (After Burov (2007))

Brittle-Plastic Properties

Brittle resistance, τ , is a linear function of normal stress, σ_n and, that is, of pressure (Byerlee 1978):

$$\begin{aligned} \tau &= 0.85\sigma_n, \quad \sigma_n \leq 200 \text{ MPa} \\ \tau &= 50 \text{ MPa} + 0.6\sigma_n, \quad 1,700 \text{ MPa} > \sigma_n > 200 \text{ MPa} \end{aligned} \quad (4)$$

Byerlee's law is equivalent of Mohr-Coulomb (Coulomb-Navier) plastic failure criterion (e.g., Burov 2007):

$$\tau = C_0 + \tan(\phi)\sigma_n \quad (5)$$

where C_0 is cohesive strength (<20 MPa) and ϕ is the internal friction angle (30 – 33°).

The Griffith criterion extends (5) to pure tensile domain:

$$\tau^2 = 4T_0^2 + 4T_0\sigma_n \quad (6)$$

where $T_0 = C_0/2$ is tension cut-off.

Viscous-Ductile Properties

Effective viscosity of the lithosphere varies from 10^{19} Pa s at the lithosphere-asthenosphere boundary to $>10^{26}$ Pa s in cold mantle near Moho depth. Several ductile mechanisms such as diffusion creep, grain boundary sliding (GBS), pressure solution, and cataclastic flow may play important role at appropriate conditions, but the leading part belongs to the dislocation creep (Kohlstedt et al. 1995).

$$\begin{aligned} \dot{\epsilon}^d &= Af_w \Delta\sigma^n \exp(-H(RT)^{-1}) \\ &\text{for } \Delta\sigma < 200 \text{ MPa (Power law)} \\ \dot{\epsilon}^d &= Af_w \exp(-H(1 - \Delta\sigma/\sigma_p)^2/RT) \\ &\text{for } \Delta\sigma > 200 \text{ MPa (Harper – Dorn law)} \end{aligned} \quad (7)$$

where $\dot{\epsilon}^d$ is shear strain rate, A is material constant, n is power law constant, f_w is water fugacity factor, $\Delta\sigma$ is differential stress, R is universal gas constant, $H = Q + PV$ is creep activation enthalpy, Q is activation energy (100 – 600 kJ/mol), P is pressure, V is activation volume, T is temperature in K. σ_p is Peierls-like stress ($\sigma_p \sim$ several GPa). For tectonically relevant $\Delta\sigma/\sigma_p$ ratios (<0.1), Harper-Dorn's flow refers to Peierls plasticity that limits rock strength in high stress regime. Dislocation creep is strongly nonlinear non-Newtonian viscous flow ($n \sim 2$ – 4).

The second most important deformation mechanism, low-stress diffusion creep (Nabarro-Herring, Coble), results from directional diffusivity of rocks under applied stress (Kohlstedt et al. 1995):

$$\dot{\epsilon}^d = Aa^{-m}f_w\Delta\sigma^n \exp(-H(RT)^{-1}) \quad (8)$$

where a is grain size and m is diffusion constant. For olivine, $m \sim 3$ and $n \sim 1$ and the constitutive law is linear Newtonian.

The Peierls super-plasticity is likely to replace Byerlee's law in the mantle below 30 – 40 km depth (Kameyama et al. 1999), that is, at high confining pressures (>1 GPa). Since Peierls plasticity includes strong water-weakening ($H = Q + p(V - \beta\Delta V_w)$), where ΔV_w is molar volume change due to incorporation of hydroxyl ions in the main rock and β is experimental parameter, it may play an important role in localization of deformation in subduction zones. This role may be shared with GBS creep, which might be responsible for aseismic localization of deformation in the lithosphere mantle.

Mechanical Properties of Oceanic Lithosphere Versus Continental Lithosphere

Due to its temperature dependence, ductile strength limits the depth to the base of mechanical lithosphere, h_m , to that of the isotherm 500 – 600 °C in oceans and 700 – 800 °C in continents (in continents, higher pressure for given temperature increases yield strength via the H term in Equation 7).

Oceanic YSEs ($0 < T_e < 50$ – 70 km) derived from (Eqs. 3, 4, 5, 6, 7, and 8) predict brittle seismogenic behavior in the upper parts of lithosphere, where depth of brittle-ductile transition, BDT, varies from few km near ridges to 40 km near subduction zones (Figs. 2 and 3). The competent domains below the elastic core are dominated by aseismic ductile creep, where important ductile strength is preserved down to the depths of 80 – 100 km near subduction zones.

Continental YSEs (0 – $5 < T_e < 150$ km) reflect strong rheological stratification between the upper, intermediate, lower crust and mantle lithosphere (Figs. 2 and 3). There might be several BDT depths, typically at 15 – 25 and 30 – 45 km (Watts and Burov 2003; Burov 2007, 2010). The depth to the mechanical bottom of strong ductile lithosphere may vary from 30 to 200 km.

T_e estimates (Fig. 3) reveal important difference between the mechanical properties of oceanic and continental lithosphere. In oceans, T_e (<70 km) follows the geotherm of 500 ± 100 °C and correlates with age. It fits into the mechanically competent core (Fig. 1).

In continents, maximal T_e values in cratons are 110 – 150 km, while T_e distribution reveals complex “bimodal” behavior (clustering around 25 – 30 and 70 km), which does not allow for geometrical interpretation of T_e . This complexity is explained by rheological stratification of continental plates, specifically of their 35 – 70 km thick crust (see entry ► “Lithosphere, Continental”). Continental plates consist of several layers of contrasting strength (upper, lower,

Lithosphere, Mechanical Properties, Fig. 3 Observed T_e distribution in oceans and continents as function of *thermotectonic age* of the lithosphere, compared to depth of geotherms of 500 °C and 700 °C defining, respectively, the mechanical base of oceanic and continental lithosphere (Burov and Diamant 1995; Watts 2001; see also “► *Isostasy*”). Assumed thermal thickness of continental lithosphere is 250 km.

Depending on assumed thermal thickness and boundary conditions, predicted depth to 500–700 °C may shift up or down by up to 25%. In continents, crust-mantle decoupling leads to ~50% T_e reduction compared to the depth to its mechanical base at 700 °C. This explains occasional correlation of T_e with 400 °C depth

Lithosphere, Mechanical Properties, Fig. 4 Mechanical and rheological interpretation of continental T_e and seismogenic layer thickness T_s (right) computed for a representative YSE as function of local plate

curvature K (left). After Burov (2010). Homogeneous horizontal stresses will shift T_e and T_s up or down in opposite directions, but will not change the character of their dependence on plate curvature

intermediate crust, mantle) that can be mechanically coupled or uncoupled. For plates younger than 200–400 Ma, T_e grows with age yet exhibiting large scatter of values between 0 and 70 km. Older plates (>500–700 Ma) are in stationary thermal regime; the age dependence of T_e is expectedly small, but T_e scatter is still strong revealing influence of factors other than thermal age. Using rock mechanics data (Fig. 4), it can be shown that continental T_e should be strongly controlled by the crustal thickness and mechanical state of crust-mantle interface (Burov and Diamant 1995). When the lower crust is mechanically strong, crust and mantle are mechanically coupled yielding a single strong layer with high T_e :

$$T_e \approx h_1 + h_2 \dots = \sum_n h_i \quad (9)$$

where h_i are thicknesses of crustal and mantle competent layers. Mechanical decoupling between crust and mantle leads to *structural weakening*, that is, dramatically smaller T_e (Burov and Diamant 1995):

$$T_e \approx (h_1^3 + h_2^3 \dots)^{1/3} = \sqrt[3]{\sum_n h_i^3} \approx \max(h_i) < \sum_n h_i \quad (10)$$

“Decoupled” T_e roughly equals to the *mechanical thickness* of strongest layer in the lithosphere. In particular, $T_e \geq h_c$ (h_c is crustal thickness) identifies mantle as the strongest layer. Based on T_e data it has been shown that continental crust is systematically mechanically decoupled from mantle, except for cratons, and that mantle lithosphere is generally stronger or at least as strong as the crust (Burov and Diamant 1995). *Numerical thermo-mechanical models* have later confirmed these assertions (e.g., Burov 2007, 2010).

Mechanical Properties of the Lithosphere and Four Modes of Horizontal Deformation

In addition to flexure under normal loads, four modes of lithosphere deformation and their combinations can develop under extensional or compressional conditions: (1) *pure shear* (extension: *McKenzie rifting model*; compression: *plate collision*), (2) *simple shear* (extension: *Wernicke rifting model*; compression: *subduction*), (3) *tensional/compressional instability* (extension: *boudinage*; compression: *folding-buckling*), and (4) *gravitationally unstable pure shear* (slow passive margins, *Rayleigh-Taylor instabilities* due to thickening of a colder and thus denser lithosphere mantle overlying hotter and thus lighter asthenosphere). Ductile properties largely control these deformation modes, including brittle fault spacing observed at surface (e.g., slow oceanic spreading centers vs. fast spreading centers). Brittle properties play an important role as well, specifically in localization of small and large-scale deformation, dyking, stabilization of cratons, transmission of tectonic stresses, and seismicity. Some of brittle mechanisms such as *low-angle faulting*, localization of large-scale *strike-slip* or *transform faults* and large-scale *dyke propagation* remain enigmatic.

Rheological stratification of continents is likely to influence the response of the lithosphere in all deformation modes. *Crust-mantle coupling* results in formation of narrow deep rifts while decoupling at different crustal levels may produce a variety of basins, from shallow large basins to narrow rifts. Under compression, *crust-mantle decoupling* plays a major role for continental subduction, UHP rock exhumation, slab detachment, formation of plateaus, or *lithosphere folding*. Lateral lower crustal flow is believed to be one of the key mechanisms affecting orogenic building and rift/passive margin formation or assuring feedback between surface and subsurface processes. For *mantle-continental lithosphere interactions*, such as *plume impingement*, the presence of ductile lower crust results in damping of the long-wavelength *dynamic topography* at surface, which is replaced by short-wavelength tectonic-scale deformation.

Uncertainties of Data on the Mechanical Properties of the Lithosphere

T_e studies play a key role in interpretation of *rock mechanics data*, allowing for parameterization of laboratory-based *flow laws* to geological time and spatial scales. Indeed, due to the large differences between time (10 orders) and spatial scales (6 orders) of the laboratory experiments and nature, *rock mechanics data* cannot be solely used to quantify the long-term *mechanical properties* of the lithosphere. Yet, since the *integrated strength B* of the lithosphere is directly related to T_e , one can use inelastic *flexural models* in combination with *rock mechanics data* (Eqs. 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10) to constrain, parameterize, and validate rheology parameters for geological timescales. In particular, one can derive YSEs that are compatible with the host of different observations such as T_e , heat flow, seismic imagery, gravity, and so on. There is generally a good correlation between the observed T_e and T_e predicted from experimental YSE (Watts 2001, Fig. 4). In oceans, T_e values scale well with *rock mechanics data* and *thermal models of the lithosphere* (e.g., McNutt and Menard 1982, Fig. 3). In continents, T_e rheology parameterization is delicate but can be done if one respects the physics of underlying processes (Burov and Diamant 1995; Burov 2010). Three types of *rheological envelopes* can be proposed for continental lithosphere: *Cratonic Jelly Sandwich*, *Jelly Sandwich*, *Crème brûlée* (with its variant hydrated *Banana Split* rheology) (Watts and Burov 2003; Burov 2010, Fig. 2). The first two types evoke strong mantle lithosphere that can be either mechanically coupled with the crust (*Cratonic type*) or decoupled from it by weak lower or intermediate crustal layer (pure *Jelly Sandwich*). These first two rheologies dominate and correspond to 80–90% of all cases, as confirmed by matching T_e predicted from YSEs with the observed T_e and mechanical models. The *Crème brûlée* rheology infers weak lithosphere mantle, and applies to few cases of hot lithospheres (e.g., *Basins and Range Province*).

Mechanical Properties of the Lithosphere and Styles of Tectonic Deformation

Important constraints on lithosphere rheology and properties come from physical considerations including *thermo-mechanical numerical models* of geodynamic processes. One can verify the validity of rheological assumptions by comparing predictions of thermo-mechanical models based on these assumptions with the observed tectonic evolution in various contexts such as collision and mountain belts (Fig. 5), rifts and passive margins, and subduction zones and lithosphere folding. The analytical and *numerical thermo-*

Lithosphere, Mechanical Properties, Fig. 5 Numerical thermo-mechanical models of long-term geological processes (here, continental collision) allow for validation of inferred rheology profiles (*Jelly Sandwich*, JS1–JS3, and *Crème Brûlée*, CB) by testing the compatibility of model-predicted and observed tectonic evolution. Models JS2, JS3, and CB have similar T_e (20–25 km) but different mantle strength, leading to

strong differences in resulting collision styles. The models show that strong mantle lithosphere is needed to drive continental subduction while strong crust cannot play same role (its low density prohibits subduction if there is no mantle drag). T_m – temperature at Moho. Colors: orange, yellow – crust; blue, azure – mantle; purple – oceanic slab. (Modified from Burov (2010))

mechanical models of geological processes show that predicted evolution is highly sensitive to rheology choices (Fig. 5). It has been demonstrated that in most cases mantle lithosphere has to be rheologically strong to insure stability of geological structures and the observed styles of deformation. In particular, stability of mountain ranges, continental *subduction* (e.g., Fig. 5, Burov 2010) and most observed *rifting modes* (Buck 1991; Bassi 1995) need initially strong mantle lithosphere with *mechanical thickness of the mantle part* more than 30–50 km. Collision models (Fig. 5) quantify relationships between the collision styles and deep lithosphere structure and rheology. They show that tectonic evolution depends not only on the integrated strength (T_e) but as much on strength distribution with depth, that is, on which particular lithological layer (upper crust, lower crust, or mantle lithosphere) provides main contribution to T_e . Rift models show that *narrow rifts* are associated with initially strong mantle lithosphere, while metamorphic core complexes “need” warm lithospheres with negligible mantle strength. Wavelengths of *boudinage* and deca-kilometric upper crustal fault spacing observed in rift zones also appear to be a direct function of the ductile properties of the underlying lower

crust. In compressional settings, observed *folding wavelengths* provide constraints on plate rheology since these wavelengths (50–1,000 km) are proportional to 5–10 times thickness of competent layers in the lithosphere and correlate with T_e values (e.g., Burov 2007).

Links Between Different Timescales: Burger's Rheology Model

The abundance of short-timescale observations such as *earthquake distributions* or *post-seismic relaxation* explains attempts to interpret these data in terms of long-term rheology. Yet, these attempts are typically based on misinterpretation of Goetze's YSEs that are valid only for geodynamic strain rates. Earthquakes and relaxation occur at locally and temporarily high strain rates that are not representative of long-term rates. Hence, the fact that continental lithosphere below Moho depth is mainly aseismic cannot be interpreted as a sign of weak ductile behavior (Fig. 4). It rather indicates that either mantle stress levels are insufficient to induce brittle sliding, or that seismicogenic *Byerlee's law* does not operate at high

pressure (>36–70 km depth), or that the frictional behavior is strain-rate dependent. At seismic strain rates (10^{16} times higher than geodynamic strain rates), the entire lithosphere acts as a brittle-elastic body and no ductile flow can occur. Strictly speaking, T_e and *maximal seismogenic depth* T_s should rather anti-correlate (Watts and Burov 2003, Fig. 4). However, T_s cannot be used to constrain T_e without knowing intraplate stress level. The fact that T_s distributions in oceans and continents are similar, while their rheological and mineralogical structures are different, adds to the argument that seismicity is primarily related to stress levels.

Post-seismic relaxation data provide controversial results yielding effective viscosities of deforming domains about 1–2 orders of magnitude smaller than *postglacial rebound* data that provide minimal viscosity (10^{19} to 5×10^{19} Pa s) of the Earth's weakest layer – asthenosphere. Since these estimates are based on inversion of *surface deformation*, they strongly depend on initial assumptions on lithosphere structure and properties, while it is impossible to determine which layer in the lithosphere relaxes post-seismic deformation. Nevertheless, whatever is this layer, the estimated viscosities appear too low for long-term properties. To explain this controversy, one can consider *Burger's model* of solids. According to this model, lithospheric behavior is described by two independent serially connected terms, one of which is *Kelvin solid* responsible for the primary creep (seismic, post-seismic) and the second one is *Maxwell solid* responsible for secondary longterm creep (geodynamic timescale). The viscosity of the first term is independent of that of the second term. In other words, the physics of deformation mechanisms activated at seismic-scale strain rates is different from that of the mechanisms acting at geodynamic strain rates.

Summary

Lithosphere has important long-term ductile, elastic, and brittle-plastic strength and is capable of maintaining (not relaxing) differential stresses at geological timescales. These properties can be accessed mainly from estimates of the *equivalent elastic thickness*, T_e , combined with *rock mechanics data*, validated by analytical and *numerical thermo-mechanical models* of geological and geodynamic processes. In oceans, T_e fits in the mechanical core of the lithosphere, but in continents, it generally does not represent any particular layer due to strong *rheological stratification*. The brittle-plastic properties of the lithosphere are governed by *Byerlee's law* to 30–40 km depth and likely by *Peierls* plasticity and/or *GBS* creep below. The ductile properties are dominated by *dislocation power-law creep*, which is strongly nonlinear and rock-type dependent. Highest *integrated strength* ($T_e \sim 100$ –150 km) is detected in cratons (*Cratonic Jelly Sandwich rheology*) where strong crust is mechanically coupled with strong mantle. In warmer

continental lithospheres, mechanical decoupling between crust and mantle leads to *structural weakening* resulting in ~50% reduction of T_e (*Jelly Sandwich rheology*). In most cases, mantle lithosphere provides main contribution to the integrated plate strength. The cases where mantle is weaker than crust (*Crème-Brûlée rheology*) refer to hot lithospheres such as metamorphic core complexes. There is probably no exploitable link between short-term deformation such as earthquake data or post-seismic relaxation and long-term properties of the lithosphere.

Lithosphere, Oceanic

James S. McClain

Department of Earth and Planetary Sciences, University of California, Davis, Davis, CA, USA

Definition

The term “lithosphere” is applied to a variety of concepts and observations, and the actual definitions for the term often depend on the type of observations made. Most generally, lithosphere refers to a strong and cool outer carapace for the Earth. It lies above a weaker, hotter, and more mobile asthenosphere. The oceanic lithosphere comprises a crustal component and a mantle component, where the latter is significantly thicker, but models for the former are better constrained. The boundary between the lithosphere and asthenosphere (LAB) is the subject of a great deal of study and controversy and remains unresolved. Models for the oceanic lithosphere are intimately connected to the ideas about the nature of LAB, and to the theory of seafloor spreading. Because the crust and upper mantle must undergo cooling as they spread away from the mid-ocean and back-arc spreading centers, it is anticipated that temperature-dependent properties of the LAB deepen as the oceanic plates age. Thus, virtually all models for the oceanic lithosphere include the constraint that it must thicken with age. Modern models allow for a maximum thickness for older lithosphere, because cooling diminishes at ages approaching 100 Ma. Constraints for thickening of the oceanic lithosphere, and the nature of the lithosphere/asthenosphere boundary, are supplied by observations of age-dependent changes in seafloor depth and heat flow, by observations of a seafloor deformation, and by a variety of seismic and magnetotelluric observations.

Introduction

The term “lithosphere” is applied to a variety of concepts and observations, and actual definitions for the term often depend directly or indirectly on the type of observations made. Most generally, lithosphere refers to a relatively strong and cool outer carapace for the Earth. The concept was initially put forth by Barrell (1914), who considered the need for a strong

outer layer of the Earth to sustain tectonic loads over geologic timescales. More broadly, the lithosphere is a cold outer layer that is physically, compositionally, and/or rheologically distinct from the warmer, next deepest part of the Earth’ upper mantle, known as the “asthenosphere.” Often, lithosphere is considered a primarily conductive boundary layer, and the asthenosphere is considered an adiabatically convective layer. Furthermore, most models lead to the conclusion that the older lithosphere is denser than the underlying asthenosphere, thus leading to a density instability that contributes to the formation of subduction zones. However, in detail, these ideas remain controversial, and full acceptance of any one model or definition remains elusive.

Ideas about the nature of the lithosphere are closely linked to understanding the nature of the lithosphere-asthenosphere boundary, or LAB (see Fig. 1). For example, as we shall see below, the LAB is often observed because the lithosphere displays higher upper mantle seismic velocities (known as the seismic “lid”), while the asthenosphere is associated with the seismic “low-velocity zone” (LVZ) that is often observed, particularly for shear waves.

The oceanic lithosphere shares many of the above concepts with its continental counterpart, but there are significant differences between the two. The term “lithospheric plate” is sometimes used to describe that part of the Earth that moves as a contiguous unit coherent plate. However, the vast majority of models for the oceanic lithosphere are intimately connected to the theory of seafloor spreading. Because the crust and upper mantle must undergo cooling as they spread away from the mid-ocean ridges and back-arc spreading centers, it is anticipated that temperature-dependent properties of the mantle and crust, including the rheology, physical properties (such as seismic velocity), and compositional changes, should deepen as the oceanic plates age. Thus, virtually, all models for the oceanic lithosphere include the constraint that it must thicken with age. Also, as we shall see, all modern models *allow* for a maximum thickness for older lithosphere, as cooling seems to slow or cease at ages approaching 100 Ma. This means that the uppermost young asthenosphere also must move along with the plate.

Constraints for thickening of the oceanic lithosphere, the nature of the LAB, and the difference between the lithosphere and asthenosphere are supplied by changes in seafloor depth and heat flow, by observations of a seafloor deformation, and by a variety of seismic and magnetotelluric observations. We look in detail at each of these below. The nature of the LAB remains controversial. Most models argue for a boundary between the completely solid lithosphere and partially melted asthenosphere. Others argue for a hydration boundary, with a lithosphere depleted in water, while the asthenosphere retains its water (e.g., Karato and Haemyeong 1998). Others argue for a boundary that includes variation in the crystal fabric of the mantle, or solid-solid transitions.

Lithosphere, Oceanic,

Fig. 1 Cartoon defining different levels of the oceanic upper mantle and crust, as used in this entry. Density is only approximate, based on the PREM model of Dziewonski and Anderson (1981). The lower boundary of the asthenosphere or low velocity zone is poorly defined for the oceans

Different authors have used the term lithosphere to be restricted to the uppermost mantle, while others include the crust. For the purposes of this entry, we shall include the crust and uppermost mantle as components of the lithosphere. The inclusion of the crust is critical, because the crust plays an important compositional role in the creation of the lithosphere at the ridges, and because the crust plays a major role in the hydration of the lithosphere as it spreads away from the axes, and dewatering of the plate as it is subducted. For this entry, we will exclude oceanic sediments, and anomalous regions such as islands, continental margins, and arcs. We include that part of the lithosphere that is generated on seafloor spreading centers and at back-arc spreading centers.

The Mantle Component of the Lithosphere

Despite the importance of the crust to lithospheric processes, it is the uppermost mantle that makes up the bulk of the observations constraining models for the lithosphere and LAB (see Fig. 1). In fact, a vast number of studies have been made of the nature of the mantle lithosphere, the mantle asthenosphere, and the boundary between them. An exhaustive review is beyond the scope of this entry, but we will try to discuss some of the key elements.

Directly or indirectly, the LAB for many models depends on temperature. While a slight change in the temperature gradient in the Earth can result in a low velocity zone in the mantle, many studies suggest that the LAB is a fairly sharp transition, and thus it is a result of a more fundamental change in the mantle. Many workers argue for a boundary between a totally solid lithosphere and an asthenosphere consisting of a small but significant percentage of melt (e.g., Anderson and Spetzler 1970; Kennett and Furumura 2015; Eilon and Abers 2017). The effects of such melt may be enhanced by its

concentration at the LAB, or by the geometry of melt layering.

However, partial melt models are not universally accepted (e.g., Karato and Park 2019). Others argue that the LAB may represent a hydration boundary (e.g., Hirth and Kohlstedt 1996; Karato and Haemyeong 1998). Other transitions have been proposed, including a change in the orientation of the anisotropy at the LAB, deformation-related grain size effects, and the presence of elastically accommodated grain boundary sliding (see Karato and Park 2019). Solid-state phase boundaries also may explain the transition.

Most of these mechanisms for the LAB are temperature sensitive, and this suggests that the depth of the LAB must change as the lithosphere ages and cools. As we shall see below, most models include such age-related changes. Many models also imply an upper limit on the thickness of the lithosphere. To the extent that these models converge, the thickness of the lithosphere (or depth to the LAB) appears to lie between 90 and 135 km.

Models Constrained by the Cooling of the Lithosphere as It Ages

Measurements of heat flow and seafloor depth are directly related to the temperatures in the ocean lithosphere, and to the changes in temperature as it ages. The ocean forms an isothermal boundary layer (near 0 °C) at the seafloor, and temperatures in the lithosphere are controlled by thermal conduction and convection of heat to the seafloor from the mantle. With the recognition of the theory of seafloor spreading it was predicted that the seafloor should contract (deepen) and heat flow should decrease as it ages. Early models focused on conductively cooled models. Davis and Lister (1974) considered a simple half-space cooling model and calculated the depth as a function of age. They show that conductive cooling of the lithosphere and resulting

contraction lead to an ocean depth anomaly (Δh) that is proportional to the square root of age and can be represented as,

$$\Delta h(t) = \frac{2}{\sqrt{\pi}} \alpha_e T_m \sqrt{\kappa t}, \quad (1)$$

where age is given by t , the thermal diffusivity of the “lithosphere” is given by κ , and the emplacement temperature of new crust and mantle ($t = 0$) is given by T_m . The effective thermal expansion coefficient, α_e , is adjusted for the replacement of rocks with lithosphere density (ρ_l), by water (ρ_w), or

$$\alpha_e = \left(\frac{\rho_l}{\rho_l - \rho_w} \right) \alpha_l. \quad (2)$$

In addition to increasing in depth, it was found that the conductive model predicts a decrease in measured heat flow (q) with

$$q(t) = k T_m \frac{1}{\sqrt{\kappa t}}, \quad (3)$$

where k is the thermal conductivity of the lithosphere. Davis and Lister (1974) and Parsons and Sclater (1977), and others, pointed out significant discrepancies between the above predictions and actual measurements made on the seafloor. The indication that seafloor depths were too deep and heat flow too low on the young seafloor was most prominent. It was suggested that hydrothermal circulation at the ridges essentially cooled the crust and upper mantle far more efficiently than conductive models, thus accounting for the observations. This was confirmed by the discovery of very high temperature venting (e.g., Corliss et al. 1979) that spectacularly confirmed the role of hydrothermal circulation in cooling the lithosphere, as well as accommodating chemical alteration of the oceanic crust (see Fig. 2a and b).

In addition to the anomalous depths and heat flow in younger plate ages, studies revealed that *older seafloor* exhibits just the opposite effects, with seafloor depths being shallower and heat flow higher than the half-space predictions (see Fig. 2a and b). These observations suggest that cooling of older (>70 Ma) lithosphere is greatly reduced or eliminated. That is, the average seafloor depth approaches a maximum, while the heat flow approaches a minimum above older

Lithosphere, Oceanic,

Fig. 2 Different observables used to constrain models for the oceanic lithosphere, primarily its mantle component. **(a)** Observed heat flow data (in red) averaged in two million year bins (modified from Stein and Stein (1992) compared to predictions for a conductively cooled half space (in gray-dashed line). Heat flow is too low and scattered for ages less about 40 Ma, indicating nonconductive (hydrothermal circulation) cooling must be taking place. **(b)** Observed seafloor depth (in blue) compared to predictions for a conductively cooled half space (in gray-dashed). Depths are too shallow beyond 80 Ma, indicating temperatures have stabilized and heat is being supplied from below. **(c)** Plot of earthquake depths and effective elastic thickness on top of expected isotherms for a half space model

lithosphere. A common explanation is that the lithosphere is a zone of conductive cooling, while the underlying asthenosphere is undergoing adiabatic convective heat flow, maintaining a limit to cooling, and thus yielding a maximum thickness to the lithosphere. Parsons and Sclater (1977) found that the model that best fit their large data set was a lithosphere-asthenosphere boundary that reached a depth of 125 km under older lithosphere, with a temperature of 1350 °C.

These early models have been greatly refined by better data sets and the inclusion of more constraints. In their widely cited paper, Stein and Stein (1992) found an improved fit for a larger data set, with an older lithosphere thickness of 95 km (± 15 km), and a weakly constrained basal temperature of 1475 °C (± 250 °C). Their model, labeled GDH1, has become a standard of comparison for more recent efforts to study the evolution of the lithosphere. Stein and Stein (1994) also considered in detail the role of hydrothermal circulation, both high temperature circulation at the spreading centers, and more diffuse and lower temperature circulation on seafloor that may persist to >60 Ma.

Afonso et al. (2007) further refined models for the lithosphere by including gravity and geoid height measurements, as well as consideration of seismic velocities as constraints on the LAB and lithosphere. In their model, they include the buoyancy effects of the crust, and the effects of solid phase transitions in the mantle, and using a basal temperature of 1300 °C to find a “thermal lithosphere” thickness of 105 km. Very important is their finding that the density of the lithosphere *may* not be greater than the underlying asthenosphere, contrary to accepted models.

Grose and Afonso (2013) consider the insulating effect of the crust, and radiative heat transport in their analysis of the temperature effects on lithosphere evolution. They find their models that include consideration of pressure-dependent thermal properties, hydrothermal circulation, and insulating oceanic crust achieve good fits to various observations. They find an asymptotic lithosphere thickness of 109 (± 6) km if a radiative contribution is small, and 123 km if it is significant. They also find significantly lower heat flow values for young ocean lithosphere, when compared to GDH1.

Korenaga and Korenaga (2016) argue that the presence of a relatively low density crust may add buoyancy to the lithosphere, not accounted for by many models. More recently, Richards et al. (2018) reexamine data after corrections for sediment and crustal thickness. They also include constraints from laboratory measurements on the temperature and pressure dependence of thermal parameters such as conductivity and thermal expansion coefficients. In their model, they predict the maximum lithosphere thickness of 135 km.

Models Constrained by Rheological Observations

One of the major concepts of the mantle lithosphere is that it behaves with a rheology that is distinct from that of the

underlying asthenosphere. Specifically, it is widely considered that the lithosphere can be defined by elastic or brittle behavior while the asthenosphere has a viscoelastic or ductile rheology. These differences have been exploited in a number of studies and give distinct values for the long-term thickness of the “lithosphere.”

It has long been known that vertical loads added to the Earth’s crust, such as volcanoes, mountain ranges, and glacial ice sheets, will cause the surface to subside. Similarly, removal of the load by erosion or melting ice will cause uplift. This leads to the concept of an isostatic compensation depth, at which the pressures exerted by the overlying loads are equal. However, if the lithosphere is strong and elastic, it can support and distribute that load over a region that is broader than that of the load applied. That is, there is less subsidence than would be normally expected. The resulting bending of the lithosphere under the load can be thought of as a response of an elastic plate overlying a viscoelastic asthenosphere. The wavelength and amplitude of bending are reflected in deviations in seafloor depth, and measurement of the seafloor can be used to determine an “effective plate thickness” (Watts 2001). This thickness is not necessarily the same as that of the lithosphere. The effective plate thickness as a function of age is shown in Fig. 2c (modified from Stein and Stein 1992). We see the equilibrium lithospheric thickness is far less than the estimates from overall seafloor depths and heat flow values discussed above, with maximum values reaching about 50 km, roughly corresponding to the 600 °C isotherm in the half-space cooling model.

Similarly, workers have considered the depth of “intra-plate” earthquakes (earthquakes occurring away from plate boundaries). The maximum depth of seismicity can be considered the boundary for brittle and nonbrittle behavior (e.g., Wiens and Stein 1983; Stein and Stein 1992), and that in turn could be considered a proxy for lithospheric thickness. As can be seen in Fig. 2C, the result yields a “lithospheric” thickness that also corresponds to the 600 °C isotherm for the half space cooling model, and a maximum thickness of about 60 km for a 100 Ma crust. However, Afonso and others (2007) argue that temperatures at the base of the seismogenic zone would be higher (700–800 °C) than those predicted by simpler models, but still much below shallower than any melting boundary.

Models Constrained by Seismic and Magnetotelluric Observations

The best information about the Earth’s interior structure comes from observations exploiting seismic wave propagation. This is true for the oceanic lithosphere and asthenosphere as well, although often in the context of high seismic velocity “lid” overlying a low velocity zone (LVZ). Thus, the characterization of the lithosphere is closely linked to the observations of the underlying LVZ, and the boundary

between them, the LAB (see Fig. 1). Over the years, the major constraints on the upper mantle structure have resulted from observations of surface waves. With the development of better and more ocean bottom seismometers (OBS), body wave phases converted at the LAB have provided new, more detailed constraints. In addition, certain diffuse seismic phases, typically labeled Po and So, are believed to be scattered P and S waves that are trapped in the lid, and they can be used to further characterize the lithosphere.

Surface Waves Studies

Seismic surface waves have long provided the firm evidence that a low velocity zone (LVZ) exists in the upper mantle between the Moho and the 400 km discontinuity (e.g., Forsyth 1975). Surface waves are primarily sensitive to shear wave velocities. Low velocity zones are frequently reported for shear waves and appear to be particularly well-defined under the oceans at a depth of 100–150 km. While not observed for all studies, the LVZ was present in models often enough to be included in for horizontally polarized shear waves (S_h) in the widely cited and used Preliminary Earth Reference Model (PREM, Dziewonski and Anderson 1981). Dziewonski and Anderson allow a negative velocity gradient with respect to depth below the Moho (Fig. 3). Vertically polarized shear waves (S_v) do not share this feature in PREM, requiring significant seismic anisotropy in the uppermost mantle. PREM includes this negative velocity gradient down to the Lehman discontinuity at 220 km, which is a

relatively sharp increase in velocity. Thus, the PREM does not include a LAB or separate lithosphere and asthenosphere.

In general, by virtue of their long wavelengths, surface wave models do not resolve details of the lithosphere-asthenosphere boundary (LAB) or of the lithosphere itself. The presence of the LVZ obviously implies a high velocity lid, however, the nature of the LAB remains controversial.

Several important features have been observed using surface waves. Perhaps most important has been the observation that the depth of the seismic LVZ increases with seafloor age (e.g., Forsyth 1975, 1977; Nishimura and Forsyth 1989) (see Figs. 3 and 4). This implies that, whatever the nature of the LAB, it must be at least partly controlled by temperature. The fact that it deepens with age, and that the lithosphere thickens with age, requires that the deeper parts of the older lithosphere initially were part of the young asthenosphere.

Burgos et al. (2014) used an inversion data set comprising some 300,000 different dispersion measurements for group and phase velocities for surface Rayleigh and Love waves. They found regional variations in structure of the upper mantle, including age-related thickening of the lithosphere. In order to quantify those changes, they chose four different “proxies” for the depth of the LAB. They chose the maximum negative velocity gradient for S_v waves (the vertically polarized shear wave velocities) as one of their proxies.

For another proxy, Burgos et al. (2014) used the azimuthal seismic anisotropy revealed by the shear wave inversions, and its relationship to present-day plate motion. Seismic

Lithosphere, Oceanic,

Fig. 3 Examples of shear wave velocities (km/s) and the log of electrical conductivity (S/m) for profiles extending through the crust and upper mantle. The Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981) is shown, for both vertically and horizontally polarized shear waves (S_v and S_h) are shown in blue. Results of Nishimura and Forsyth (1989) are shown in red for two different ages in the Pacific, and a conductivity profile for the NoMELT experiment is shown in Green (Evans et al. 2019)

Lithosphere, Oceanic, Fig. 4 Lithosphere-Asthenosphere Boundary (LAB) depth for a variety of seismic studies using different techniques. We also include one magnetotelluric experiment result. Regardless of the technique, all of the studies are consistent with the concept of a lithosphere that thickens with age because of progressive cooling of the upper oceanic mantle. Most allow models where cooling is reduced or ceases in lithosphere older than 100 Ma. Burgos et al. (2014) used surface waves, and a variety of proxies to represent the boundary. Included here are results using the maximum shear wave negative velocity gradient (for vertically polarized shear waves) (Vs). Another of their proxies was the

transition from azimuthal anisotropy (Ψ) (see text), which gives a slightly deeper LAB at older ages. Nishimura and Forsyth (1989) also use surface waves to define a LAB. Hannemann et al. (2017) used instrument receiver functions to determine LAB depth beneath the Atlantic. The Rychert and Shearer (2011) results were from shear body wave multiples (SS) reflecting from the LAB. We have only replotted their results from “normal” plate locations. Shito et al. (2015) modeled propagation of phases (Po and So) propagating in the lithosphere to constrain LAB depths. Evans et al. (2019) present an estimate of LAB depth from a magnetotelluric survey southeast of Hawaii

anisotropy both for compressional (P) and shear (S) waves has been widely observed in the oceans, particularly for the uppermost mantle (e.g., Raitt et al. 1971; Blackman and Kendall 2002; Lin et al. 2016). In the lithosphere, it is widely accepted that the anisotropy coincides with the preferred fabric of olivine in the mantle rocks. This preferred fabric is the result of strains related to plate motion at the time for formation; it is “frozen” in and preserves a record of plate motion during formation at the ridge axis. For the more fluid asthenosphere, they suggested that the anisotropy could change and reflect the present-day deformation, perhaps related to subsequent changes in present-day plate motion or to other smaller scale convection. Thus, they choose the depth where the anisotropy diverts away from present-day plate motion as the depth of the LAB.

Burgos et al. (2014) find that both of the above proxies, as well as others, reveal a deepening of the LAB with age from 0 to 150 Ma. However, it is important to note that different proxies give different depths, again illustrating the problem of defining what is meant by the term “lithosphere” (see Fig. 4). For example, Burgos found a mature lithospheric thickness of about 110–120 km for the proxies shown in Fig. 4, but he also found using the maximum radial anisotropy as a proxy led to a lithospheric thickness of 70–80 km.

In addition to seismic velocities, a number of studies have shown that the seismic LVZ roughly correlates with a zone of high seismic attenuation (or low Q) (e.g., Anderson and Hart 1978; Eilon and Abers 2017). The lithosphere or lid forms a zone of low attenuation or high Q. Hammond and Humphreys (2000) argue that attenuation measurements argue for a partial melt in the asthenosphere, and thus in their model the LAB is the melt boundary.

Studies Using Seismic Body Wave Phases

All of the above-discussed observations share in the fact that the depth resolution of resulting models is poor because of the long wavelengths required for deeply sampling surface waves. This characteristic tends to “smooth out” boundaries if they are present (see the excellent review of Karato and Park (2019) for more detail). Such smooth boundaries are consistent with changing varying variables such as pressure and temperature. For example, in the absence of any other type of transition seismic, velocity gradient will depend on the ratio of the pressure gradient to the temperature gradient. Higher pressure gradients will drive the seismic velocity gradient positive, while higher temperature gradients will lead to a negative velocity gradient. The critical temperature gradient is about 6.5 °C/km (Birch 1952), and with a correction for the

Earth's curvature, the critical gradient is about 8.5 °C/km. These are quite reasonable geotherms for the mantle.

In recent years, new advances in ocean instrumentation and data analysis techniques have improved our understanding of the oceanic upper mantle. New techniques allow studies of faint seismic body wave arrivals that may provide better vertical resolution than those provided by surface waves studies.

Many recent studies have made use of the so-called “instrument response functions” to improve the resolution for models for the lithosphere, asthenosphere, and LAB. Such studies exploit the body waves traveling nearly vertically to a receiving seismometer or array of seismometers. As the body waves intersect a boundary, conversions between P waves and vertically polarized shear waves (Sv) may occur. In general, only a fraction of the incident wave energy will be converted. The size of these converted phases depends on the sharpness and velocity changes across the boundary. The resulting phases are denoted P_s (where a small fraction of the incident P wave converts to a shear wave at a target interface) and S_p (S to P conversions). For the former, the arriving P wave will be followed by a low amplitude shear wave for stations that overlie the targeted boundary. In the case of S_p , the arriving shear wave will be preceded by a low-amplitude P wave that formed at the boundary.

Such converted phases can be difficult to discern from scattered energy, but with proper processing of the resulting seismograms, they can be detected and analyzed. For example, Kawakatsu et al. (2009) argue that such conversions observed in the western Pacific require a sharp LAB that cannot be explained by gradual temperature/pressure variations. They argue the data require a LAB to be less than 15 km thick and include a velocity reduction of 7–8%. The large change leads them to suggest that boundary's effect is enhanced by partial melt that occupies horizontal layers. Such a sharp boundary probably precludes simple changes in temperature gradient as the cause of the lithosphere-asthenosphere boundary.

Hannemann et al. (2017) made a careful study of potential P to S conversions for a broad-band seismic array deployed in the Atlantic over 79 Ma lithosphere. Using a variety of techniques, they attempted to identify P_s conversions for the mantle, using data for both single stations, and stacked data from multiple stations. They made a tentative identification of the LAB for single-station data. If correct, it suggests the LAB is 70–80 km deep (see Fig. 4), and also argues for a relatively sharp transition.

In addition to converted phases, a number of workers have examined precursors to shear wave arrivals such as those reflected from the core (ScS) or from the surface (SS) (e.g., Goes et al. 2013). Rychert and Shearer (2011) examine differences between SS phases reflecting from the Earth's surface and those that may reflect from the LAB. Those

differences will be subtle. However, they can be enhanced by stacking multiple seismograms from ray paths that reflect from the LAB at similar geographic locations and ages. They find that the LAB thickens with age as expected, but at depths corresponding to temperatures of 820–1020 °C (see Fig. 4). Rychert and Shearer (2011) allow for, but do not necessarily prove, the presence of a sharp boundary. They suggest the IAB may correspond to a hydration boundary, a melt boundary, or a permeability boundary. However, these temperatures are low for normal melting.

Other Geophysical Studies

Additional constraints about mantle lithology are derived from the response of the Earth to electromagnetic induction caused by long wavelength electromagnetic waves that are vertically incident from sources such as fluctuations in the Earth's magnetosphere or lightning strikes trapped by the ionosphere. In these studies, the asthenosphere correlates with a high conductivity zone (e.g., Evans et al. 2019) (see Fig. 3), while lithosphere would be represented by relatively high conductivities.

In addition to the importance of seismic surface waves and body waves, observations have been made of unusual compressional (Po) and shear (So) phases that seem to be trapped in the lithosphere. These are typically characterized by a long, diffuse coda that follows the initial P and S waves propagating along the Moho. They tend to be of very high frequency compared to regular body wave phases. (Note there is some confusion of notation. Some workers specify these waves a Po and So, while some use notation as Pn and Sn. We use the former notation, and restrict the use of Pn and Sn for the first arriving mantle phases, that tend to be low amplitude.)

Po and So are most prominent for over long travel paths, indicating that reverberation in a high Q medium, such as the lithosphere, is important. Sereno and Orcutt (1987) point out that reverberation in the water and sediment columns may also contribute to the complexity of the coda. However, Kennett and Furumura (2013) and Shito et al. (2013) argue for a propagation path best represented by scattering from three-dimensional heterogeneities. Kennett and Furumura (2015) model both Po and So phases using a stochastic model for the scale of heterogeneities. They find that scattering from “quasi-laminate” features with a horizontal characteristic scale of 10 km, and vertical characteristic scale of 0.5 km, provides the best fit.

More work is needed in the study of these phases, but they do provide constraints of a lithospheric thickness. Using synthetic seismogram modeling, Shito et al. (2015) found that these trapped phases generated by earthquakes in the western Pacific demonstrate a systematic thickening (to 80 km.) of the lithosphere with age to at least 50 million years (see Fig. 4).

The Crustal Component of the Oceanic Lithosphere

The top few kilometers of the oceanic lithosphere comprise the ocean crust. To a first approximation, the crust is viewed as the mafic member of the lithosphere and is generated by processes at the mid-ocean ridges (or at back-arc spreading centers). Three lines of evidence dominate our knowledge of the crust. These include direct sampling of seafloor rocks where they are exposed, seismic experiments that reveal the seismic velocity structure of the crust, and the study of crustal analogues exposed above sea level. These studies have converged on the so-called Penrose or “ophiolite” model (Fig. 5). While this model is highly successful in its predictions, the research in the last 20 years has led to the recognition, at least for some crust generated at ridges with slow to ultra-slow spreading rates, that the ophiolite models must be revised to include newly discovered crustal features.

Samples of Crustal Rocks

Oceanic crustal rocks are generally recovered from near the mid-ocean ridges before sediments have a chance to accumulate on the aging seafloor. The vast majority of these rocks are mafic basalts, however, other rocks such as gabbros and serpentinites are sometimes exposed at transform faults or on rifted mid-ocean ridges.

From the Challenger expedition in the 1870s until the 1980s, most seafloor samples were collected by dredging, where a chain bag, with a steel jaw, is dragged behind a drifting or slowly moving ship. The problem with dredging, in addition to the uncertainty of success, is that because the

ship was towing the dredge bag, it was never certain where the dredge was when it collected the sample.

Recently, more precisely located samples have become possible through the use of well-navigated submersibles and remotely operated vehicles (ROVs). The location of these vehicles, and any samples they recover, can be determined very precisely through acoustic techniques and the use of GPS in the ship above. In addition, a relatively new technique, rock coring or “wax coring,” has gained usage. With this tool, a weight is lowered rapidly from the ship, nearly straight down. The turnaround time is rapid compared to dredging or submersibles, so numerous samples can be collected. Because the corer is dropped straight down, rather than dragged, the location of the samples can be determined from the ship’s GPS position. The samples are small and usually volcanic glasses from the surface of the seafloor basalts, and with newer analytical tools and techniques, they can be analyzed for the detailed chemistry of the glass.

Regardless of the sampling method, all of the samples are examined and described on the ship. When they are returned shore, they undergo extensive and higher precision analysis using a variety of techniques. Even from the earliest studies, basalts are the most commonly observed rock type, and they result from partial melting of ultramafic peridotites in the mantle.

For rocks recovered that originated on the mid-ocean ridges, the vast majority are so-called MORBs or mid-ocean ridge basalts. MORBs are characterized by a composition that includes depletion in the incompatible elements (e.g., K, Ti, P, Ba, Pb, Th, U, Zr, Rb, and Sr) and light rare earth elements (atomic numbers between 57 and 71). These observations,

Lithosphere, Oceanic,

Fig. 5 Comparison of seismic velocities with an idealized ophiolite, and with drilling results for two Pacific ODP (504b) and IODP (1256d) drill holes that successfully penetrated to midcrustal levels (modified from McClain 2003). The seismic structure is for a specific profile on 16 Ma crust generated on the fast spreading southern East Pacific Rise. The midcrustal inflection is used here as the boundary between layer 2 and layer 3 for this particular crustal model. The inflection could be caused by the lithological boundary between sheeted dikes and gabbros as shown here, and/or by changes in porosity or metamorphic grade. From velocity alone, we cannot tell. However, all three causes could occur at the same depth

coupled with a relatively low $^{87}\text{Sr}/^{86}\text{Sr}$ ratio, indicate that the mid-ocean ridge basalts originate from partial melting of a depleted upper mantle beneath the ridges. An additional constraining factor from seafloor basalts was that the detailed composition required that magma undergoes partial fractionation at shallow (i.e., lower crustal) pressures. This led to models that included a magma chamber in the lower crust.

With the improved analytical instrumentation and techniques, the compositions of MORBs have been further parsed into N-MORB (normal-MORB) and E-MORB (enriched-MORB), and intermediate compositions (transitional or T-MORB). These observations generally are interpreted to indicate they originated in a heterogeneous, but still depleted, mantle source.

Ophiolites, Ocean Drilling, and the Ocean Crust

Ophiolite sequences have been studied for over 100 years and have been the source of substantial controversy. Complete ophiolites (see Fig. 5) include a coherent stratigraphy extending from submarine lava flows into sheeted dikes, representing the feeders for the lava flows. Beneath the sheeted dikes are gabbros, often divided between isotropic gabbros (no preferred fabric) at the top, and layered (cumulate) gabbros at the base. Beneath the gabbros are ultramafic peridotites, varying between harzburgites, lherzolites, and dunites. In general, the peridotites are serpentinized to a greater or lesser extent, but it is unclear whether the serpentinization occurs during the original formation of the crust at the mid-ocean ridges or during emplacement and uplift onto land.

Early on, ophiolites were thought to originate as oceanic crust and uppermost mantle, and to have been thrust up onto the continents by convergent processes (see, Moores 1982). Substantial debate centered on whether particular ophiolites originated in arc or back-arc settings, or whether some may have originated on midocean ridges. The former argument is primarily based on the detailed geochemistry of the ophiolite lavas, which seem to mimic those dredged from arcs. In contrast, some ophiolites are stratigraphically overlain by pelagic sediments, with no evidence for the volcanoclastic sediments observed in arc settings.

Regardless of the origin of any particular ophiolite, it is clear that ophiolites provide an important analog for ocean crust generated on midocean ridges. The presence of sheeted dikes to deliver magma from a crustal magma chamber, and the presence of gabbros originating from the freezing of the magma chamber, leads to a model that is consistent with the petrologic models derived from seafloor sampling as described above.

The Ocean Drilling Project, its predecessor Deep Sea Drilling Project, and successor the Integrated Ocean Drilling Project provide support for the “ophiolite” model. In particular, drilling results in the Costa Rican rift (Hole 504b) and off

southern Mexico (Hole 1257) have penetrated through the seafloor lavas and into the sheeted dikes. For the latter site, gabbros intercalated with sheeted dikes have been reached at the base of the sheeted dike column.

Seismic Studies of the Ocean Crust

Except for studies of subareal ophiolites, rare exposures on the seafloor, and a few deep drilling efforts, seismic studies provide the only information about the oceanic crust below the seafloor. They provide information on structure and seismic velocities that lead to inferences about the petrology of the upper mantle and crust.

After World War II, marine institutions began to exploit the seismic refraction technique to explore the Earth beneath the sea. These experiments usually yielded observations of compressional or P-wave seismic velocities, although converted shear waves were sometimes observed, and shear velocity structures could be inferred. In these early studies, theoretical and computational tools necessarily restricted models to laterally homogeneous structures, and a consistent four-layer model for the crust and overlying sediments was developed (e.g., Shor et al. 1969). The first layer was that of sediments, with velocities averaging about 2 km/s. Beneath that was “Layer 2,” and because the seafloor was known to reveal lavas in unsedimented areas, it was expected that layer 2 was the “volcanic layer.” The thickest part of the oceanic crust is “Layer 3,” with velocities of about 6.8–7.2 km/s and thicknesses on the order of 2–4 km. The lithology of layer 3, also known as the “oceanic layer,” has been controversial, with some models preferring a gabbroic composition, and others a serpentinite composition. The former model has gained general acceptance, partly because of the presence of gabbros in ophiolites (e.g., Christensen and Salisbury 1975; McClain 2003). Underlying layer 3 is layer 4, with compressional wave velocities of about 8 km/s, and corresponds with the upper mantle. The lithology of the mantle is generally taken to be peridotite, consistent with the above-mentioned models for partial melting of the mantle leading to the rise and formation of a mafic crust. Thus, the crust comprises layers 2 and 3, and the boundary between the crust and mantle, layers 3 and 4, is known as the Moho or Mohorovicic discontinuity.

With better experiments, the original four-layered model was parsed into more finely divided structures. The earliest refinement was the observation of “Layer 2A.” This was the shallowest and lowest velocity portion of the upper crust, and the low seismic velocities were attributed to the high porosities of basalt flows. This interpretation is further supported by the observation that the velocities of layer 2A tend to increase to normal layer 2 values. That leads models where layer 2A thins over a few million years. This was interpreted as infilling of pores by metasomatic precipitation of minerals as the crust ages (e.g., Houtz and Ewing 1976). Such an explanation

requires fluid circulation and chemical alteration in the crust that must continue over millions of years after the crust forms.

In the 1970s, the development of new theoretical and computation tools allowed workers to move beyond the simple layered models to those that continuously vary, but usually vertically stratified models. As models grew more sophisticated, it became possible to correlate them with ophiolite structures, using both velocities and thicknesses (e.g., Christensen and Salisbury 1975; McClain 2003), and the so-called Penrose model or “ophiolite model” for the oceanic lithosphere has become the accepted (Fig. 5). For the crust, this led to models where Layer 2 was divided into an upper zone with relatively low velocities (layer 2A) discussed above, underlain by a high velocity gradient extending to layer 3. The high-gradient zone, sometimes labeled layer 2B, was attributed to a decrease in crustal porosity and is correlated with the transition to sheeted dikes of the ophiolite model.

At mid-crustal levels, some experiments revealed a slight inflection in seismic velocities between the lower and upper crust (layer 2 and layer 3), while others did not (see Fig. 2). The origin of this slight transition was (and is) attributed either to a metamorphic boundary between lower and higher grade metasomatic changes in lithology, or to a transition from diabase dikes to the gabbros in the lower crust. Finally, the Moho is more gradational in these refined models, and the mantle velocities are well correlated with those expected for peridotites.

The Midocean Ridges

The oceanic crust is generated by a complex interaction of magmatic, tectonic, and hydrothermal processes that take place at the midocean ridges where seafloor spreading occurs. The end result, at least on intermediate- to fast-spreading ridges, should be an ophiolite-like structure. The majority of seismic, petrological, and observational experiments over the last 2–3 decades have focused on the tectonic plate boundaries, with particular attention on the ridges. Interpretation of the data from these studies required models that allowed for two- or three-dimensional structure, rather than the laterally homogenous models from earlier. This required a breakthrough in seismic studies. Early ray-tracing techniques have given way to more robust tomographic inversion. In addition, the development of longer seismic hydrophone streamers and new processing and imaging algorithms now permits detection of subbasement (crustal and upper mantle) reflections using multichannel reflection experiments.

One of the critical controversies about the structures beneath midocean ridges was the presence of a seismically resolvable axial magma chamber (AMC). As stated above, petrologic data seemed to require some sort of magma chamber in the lower crust, and the ophiolite model includes a thick gabbro layer. However, models resulting from seismic

refraction surveys were equivocal, with some revealing crustal AMC (e.g., Orcutt et al. 1975). McClain et al. (1985) were able to provide convincing evidence for a narrow magma chamber on the East Pacific Rise at 13° north. The seismic velocity required for the chamber was 4.5 km/s, suggesting a partial melt rather than a pure magma. Further evidence was that the resolved AMC was found in an extensive tomographic experiment on the East Pacific Rise at 9°30'N (Toomey et al. 1990).

For fast-spreading ridges, the question of magma chamber existence was largely resolved when a large multichannel experiment was conducted along the northern East Pacific Rise (e.g., Detrick et al. 1987). Using the long hydrophone streamers, researchers were able to resolve reflections from the base of Layer 2A, as well as the Moho. However, most striking was the presence of a reflection at midcrustal levels along most of the length of the ridge. Analysis of the reflection amplitude and the change in the sign of the reflection require that the reflections result from a sudden decrease in seismic velocity, and the explanation for this velocity inversion was the presence of an axial magma chamber. Furthermore, the large amplitudes of the reflections require a rather low velocity compared to models obtained from refraction experiments. This suggests that reflections result from pure or nearly pure melt sills. The discrepancy results because refraction experiments do not resolve the sills, but instead image an average structure made up of the sills and partial melt zones. Early models have suggested these sills form at the top of the magma chamber, and may be responsible for the isotropic gabbros observed in some ophiolites. The larger partial melt zones would form the cumulate gabbros that make up the bulk of the lower crust.

Subsequent to the initial experiment of Detrick et al. (1987), similar magma reflections have been imaged on other segments of the fast or ultrafast spreading East Pacific Rise (e.g., Singh et al. 2006), as well as ridges with intermediate spreading rates (e.g., Canales et al. 2009). Most studies suggest that the crustal AMC is generally narrow.

Hydrothermal Activity

One of the most spectacular discoveries in the annals of earth science was the observation of vigorous hydrothermal circulation at spreading centers (e.g., Corliss et al. 1979). While the presence of hydrothermal circulation was not surprising, the exceptionally high temperatures, the deposition of hydrothermal minerals, and a vigorous chemosynthetic biological community were a major breakthrough in the study of midocean ridges. It is clear that the chemical, biological, and geological contribution of these vents is felt throughout the world's oceans. Thus far, over 200 hydrothermal vent fields have been discovered, and as many as 1000 may lie on the world's midocean ridges (Baker and German 2004).

Early studies suggested that a substantial portion of the Earth's heat was lost along the high temperature hydrothermal circulation on midocean ridges. More recent analyses indicate that more heat is lost through lower temperature circulation in older crust. However, it is clear that near-axis circulation is a major component of the crust forming process, and their discovery has led to a new appreciation for the interdisciplinary nature of midocean ridge science.

High temperature venting is observed on all ridges, and at all spreading rates. Such systems require a heat source and a permeability structure that permits a focused flow of fluids to the surface. For fast-spreading ridges, heat sources are plentiful, with the presence of axial magma chambers and frequent eruptive events. Indeed, the narrowness of the axial magma chamber requires that circulation penetrates at least to the top of the chamber and/or into the gabbros at its flanks (e.g., Lister 1983). The geometry of the down-going limb of the seawater into the crust remains uncertain. It may be that it penetrates along-axis, perhaps along faults or fissures, or it may penetrate from the sides, also along small normal faults.

For slower spreading ridges, the heat source is unclear. Certainly volcanic eruptions do occur, so a heat source is present at least some of the time. However, it may be that water also can penetrate to the deeper hot, but not molten, mantle rocks. The large normal faults often present on slow spreading ridges may accommodate this deeper penetration.

Along-Axis Variations in Ridge Processes and Slow-Spreading Ridges

It has long been known that midocean ridges display a systematic variation in cross-sectional topography, varying from rifted ridges, with rift valleys of 1–2 km deep, and nonrifted ridges that display topographic highs. In general, rifting is associated with slower-spreading ridges, while nonrifted ridges exhibit rapid seafloor spreading. There are a number of exceptions to the rule. For the Reykjanes Ridge adjacent to the Iceland Hot Spot, the slow-spreading ridge is unrifted, and on the Galapagos Ridge the ridge segments closest to the hot spot also are unrifted. For ridges spreading at intermediate rates, both rifted and unrifted ridge segments are observed (e.g., the Gorda and southern Juan de Fuca Ridges) and are often separated by only a transform fault.

These observations suggest that the presence or absence of a rift valley is more likely controlled by magma supply. On slow spreading ridges, where the isotherms are narrow, less melt may reach the surface unless excess temperatures and magma are supplied by a nearby mantle plume. For intermediate spreading ridges, local variations in magma supply, perhaps along-axis flow, may influence the formation of a rift valley.

With the advent of multibeam bathymetric systems, it was found that ridges are segmented on a variety of scales, with offsets between segments also varying in character and

length. Macdonald and Fox (1988) described a correlation between segment depths and cross-sectional geometry, and they suggested that these variations were linked to focused magma supply at segment centers and subsequent magma flow along axis to the segment ends. It is logical to assume that the magma supply would be tied to the resulting crustal structure and thickness, with thicker crust at the centers. The seismic reflection results of Detrick et al. (1987) seemed to support that linkage. However, it appears very little correlation or variation in thickness for spreading rates greater than 30 mm/year, and it appears that segmentation does not have a major influence on crustal thickness. For ridges that spread slowly, or very slowly, crustal thicknesses are far more variable.

With the improvement of techniques, midocean ridge researchers have been able to overcome the complexities caused by topography on rifted ridges. For such ridges, typically spreading at slow rates, crustal thickness is closely tied to location along a segment, and it is likely that magma and mafic crust production are enhanced at segment centers. Tolstoy et al. (1993) correlated a thick crust in the shallow center of a rifted segment on the midAtlantic with gravity “bulls eyes,” or negative values centered at its center. The crust is thin at the segment ends, where the ridge intersects a transform.

The observation is that thin crust exists at the intersections of rifted ridges and transforms, where we expect the lowest mantle temperatures, and a suppressed magma supply (e.g., Cannat 1996). The discovery of oceanic core complexes, with exposures of gabbro and/or peridotite on the seafloor, provided observational support models for “new” crustal processes at ridges with slow to ultra-slow spreading centers (Cann et al. 1997) (see Fig. 6). It was recognized that the ophiolite model may not suffice for such locations. Instead, one has to incorporate substantial rifting that dissects the crust, and exposes the lower crust and upper mantle. This rifting leads to a complex laterally heterogeneous structure in the oceanic crust and upper mantle (e.g., Canales et al. 2008).

It appears that magma intrusions are not continuous beneath oceanic core complexes, and gabbros may not form a continuous layer as it does for the ophiolite model. During nonmagmatic rifting phases, we would argue that the mafic crustal thickness could be zero; i.e., the mantle peridotites exist at the seafloor. However, depending on the depth of serpentinization in the peridotites, with the consequent lowering of velocities, the seismic crust (velocities less than or equal to 7 km/s) may have a nonzero thickness (Fig. 6). The discovery of spectacular, serpentine-hosted hydrothermal circulation, at least one core complex, confirms the importance of rifting and serpentinization on the slow and ultra-slow spreading ridges (Kelley et al. 2001). It is clear that models for the oceanic crust must be refined to allow for slow to ultraslow spreading rates.

Lithosphere, Oceanic,

Fig. 6 Cartoon of rift-dominated processes on slow or ultraslow spreading ridges. Substantial normal faulting along a detachment fault exposes the deeper gabbros and peridotites, as volcanic/magmatic processes cannot “keep up” with the rifting. Rock units are the same as those in Fig. 5. Serpentinization of exposed or shallow peridotites will slow the seismic velocity, perhaps to crustal values. Thus, even where there are no crustal rocks, a thin “seismic crust” may be observed

Summary

The oceanic lithosphere forms the relatively cool and strong surface layer under the oceans, and it has been the subject of numerous studies and speculation over many decades. It includes two components, the crust and uppermost mantle. However, a strict description and characterization of the lithosphere remains elusive and depends on the types of observations that are used to constrain models.

Higher seismic velocities, low seismic attenuation, and low electrical conductivity characterize the mantle component of the lithosphere. It is underlain by an asthenosphere that is characterized by lower seismic velocities (the seismic low velocity zone), higher seismic attenuation (low Q), and higher electrical conductivity. The boundary between lithosphere and the asthenosphere deepens with age, i.e., the oceanic lithosphere thickens with age, a product of cooling of the plate as it spreads away from the ocean spreading center. That cooling continues for some distance but appears to decrease or cease when the lithosphere has aged on the order of 100 million years, after it has reached a thickness of 80–140 km. These maxima suggest that temperatures at the base of the older plate are maintained by convection in the asthenosphere.

The oceanic crust represents the mafic component of the lithosphere and is generated by a complex interaction of magmatic/volcanic processes, tectonic processes (seafloor spreading), and hydrothermal processes. The “competition” between magmatic processes that build the crust and rifting processes that spread the ridges is age dependent. At intermediate to fast spreading ridges, the crust is best described by the so-called “Penrose” model with a consistent igneous stratigraphy (see Fig. 5). For slow to ultraslow spreading ridges, the

crust is laterally heterogeneous as rifting brings deeper layers of the crust to or near to the surface.

Definition

Lithosphere

The outermost shell of the Earth that is sufficiently strong to support long-term geologic loads and transmit stress. These properties are attributed to low temperature and possibly to composition.

Asthenosphere

The mobile layer underlying the lithosphere where heat transfer is dominated by convection. Its properties are attributed to high temperature and trace quantities of water.

Plate tectonics

Lateral motion of large intact pieces of lithosphere (plates) that include both continental and oceanic regions. Mountain building, volcanoes, and earthquakes are the consequences of the relative motion between plates at their convergent, divergent, and transform boundaries.

Boundary-layer cooling

Conductive cooling of an initially hot semi-infinite medium, applied to the vertical cooling of aging oceanic lithosphere created at a seafloor spreading center.

Plate cooling

The description of the cooling of an initially hot layer of uniform thickness having a lower boundary maintained at a uniform temperature.

Rayleigh number

A dimensionless number reflecting the ratio of the forces driving and resisting convection.

Nusselt number

A dimensionless number reflecting the vigor of convection, equal to the ratio of the total heat transport relative to the transport that would take place by conduction alone across the same temperature differential.

Introduction

The thermal structure of the oceanic lithosphere is of profound importance. One of the dominant mechanisms of heat loss from the Earth is the creation at seafloor spreading centers and subsequent cooling of oceanic lithosphere. Ocean lithosphere constitutes roughly 60% of the Earth's surface, and the total heat flow through its surface comprises more than 80% of the global mantle heat flow (i.e., excluding the contribution from radiogenic heat production in continental crust; Jaupart et al. 2007). The thermal structure of the lithosphere plays key roles in constraining the rigidity and ultimate strength (seismic rupture potential) of the outermost layer of the Earth and influencing many geodynamic processes including the Earth's most fundamental and defining one, plate tectonics. Driving forces for the motion of tectonic plates, and numerous consequent geological processes, are derived from the integrity and density of the oceanic lithosphere as controlled to a large degree by its thermal structure. And the volume of ocean basins, and hence the continental freeboard relative to sea level, is influenced directly by the thermal structure of oceanic lithosphere.

“Lithosphere” has multiple meanings. It was first defined as the outer layer of the Earth, including the crust and upper mantle, having sufficient strength to support loads such as those imposed by mountains, volcanoes, and major river deltas (Barrell 1914). It was later identified as the high seismic velocity lid that overlies a deeper low-velocity zone in the mantle; its base was inferred to correspond to the closest approach of the geotherm to the mantle melting temperature (Gutenberg 1959). More recently and most fundamentally, it has become a geodynamic term that refers to the part of the mantle that forms relatively rigid plates, and within which

heat is transported by conduction. Flexural strength, long-term immobility, seismic properties, and possibly composition all are properties that are used to define the lithosphere and its thickness, and all are tied to temperature. Beneath the lithosphere is the relatively mobile asthenosphere, where heat transport is dominated by vigorous (high Rayleigh number, high Nusselt number) convection. The oceanic lithosphere forms a thermomechanical upper boundary layer to a “conveyor-belt” convection system, in which the Earth’s interior heat is liberated through the seafloor as the layer moves laterally away from the locus of formation at a seafloor spreading center and is absorbed by the cooled layer when it sinks back into the asthenosphere at a subduction zone. Convection in the asthenosphere is to a large extent decoupled from the lithosphere. It is characterized by Rayleigh and Nusselt numbers of the order of 10^7 and 200, respectively, and is driven both by cooling at the top by heat lost through the lithosphere and by heating from the bottom and internally by deep and distributed sources derived from secular cooling and radiogenic heat production.

Oceanic lithosphere includes a c. 7-km-thick basaltic oceanic crust, a product of partial melting of the upper mantle at a seafloor spreading center, and underlying upper mantle that has been cooled by an amount that gives the material its short- and long-term mechanical and elastic properties that contrast with those of the underlying mobile asthenosphere. Contrasting composition, resulting from the refractory process of producing the oceanic crust and from water extraction during asthenospheric ascent, may also play a part in defining the properties of the oceanic lithosphere. These various aspects are summarized schematically in Fig. 1. Previous reviews can be found in Davis (1989) and Jaupart and Mareschal (2007).

Key Observations

Because the creation and cooling of ocean lithosphere is a transient process, observations used to constrain its thermal structure are most commonly placed in the context of lithospheric age and considered in the context of a model for transient cooling. Various observations are discussed in this section, and theoretical models are discussed in the next.

Heat Flux

Heat flux through the seafloor provides the most direct constraint on the thermal structure of the underlying lithosphere, although observational uncertainties are often large (Fig. 2a). Detailed studies of the thermal regime just below the seafloor commonly reveal a hydrologic regime that in young areas is dominated by high Rayleigh- and Nusselt-number pore-water convection (see discussions in Harris and Chapman 2004 and

► [Heat Flow, Seafloor: Methods and Observations](#) entry, this volume), with high permeability in the uppermost few hundred meters of young igneous crust resulting from the volcanic and tectonic processes involved in crustal creation. Hydrothermal alteration of the crust slowly reduces the permeability, but the effects of convective heat transport are observed to persist for tens of millions of years (Von Herzen 2004). Heat passing advectively through the seafloor is virtually impossible to assess quantitatively and often goes unrecognized. Hence, wholesale compilations of seafloor heat flux observations are strongly biased (e.g., Stein and Stein 1992), particularly in young, sparsely sedimented areas where igneous crustal outcrops, serving as permeable ventilation points, are common. Where thick and extensively continuous accumulations of low-permeability sediment are present, advective ventilation ceases, and the heat flow becomes fully conductive and thus measurable. If circulation within the igneous crust persists, however, local heat flux variations can still be present, and large numbers of measurements must be made over a large area to obtain a meaningful average of the conductive seafloor heat flux at any given age.

To avoid the biasing effects of advective heat loss, two approaches have been used. Values from global data sets have been selected to be far from areas of basement outcrop (relying on statistics for a reliable mean to emerge; e.g., Sclater et al. 1976; Hasterok et al. 2011). A more direct approach involves surveys carried out with large numbers of observation points positioned carefully in context of local and regional sediment/igneous hydrologic structure to rule out effects of ventilation and properly account for the effects of sub-sedimentary fluid flow that produces scatter (e.g., Lister et al. 1990; Davis et al. 1999; Fisher et al. 2003). From such studies, a reliable relationship between lithospheric heat flux and age has emerged, with heat flux decreasing proportionately with age^{-1/2} out to an age of roughly 100 Ma (Fig. 2b) and becoming fairly constant at greater ages at roughly 48 mW m⁻².

Seafloor Depth

The most reliably measured consequence of lithospheric cooling is seafloor subsidence (Fig. 3a). Whereas heat flow determinations are affected by hydrothermal circulation in the upper oceanic crust, seafloor subsidence with increasing age away from a ridge results from lithospheric thermal contraction and hence reflects the integrated temperature state of the entire lithosphere. Bathymetry thus provides a robust constraint for understanding lithospheric thermal structure.

As in the case of seafloor heat flux, seafloor depths must be considered with some care, with attention given to several potential perturbations. This vigilance requires checks on

Lithosphere, Oceanic: Thermal Structure, Fig. 1 Schematic illustration of the creation and subsequent thermal evolution of oceanic lithosphere (a). Mechanical properties of the lithosphere are likely influenced primarily by temperature (brown shading) and possibly composition (light gray shading). Red arrows depict the migration of partial melt supplying crustal formation. Dark red arrows depict three modes of convection in the asthenosphere, including (1) upwelling beneath migrating lithosphere wherever it is thickening, (2) small-scale convection driven by cooling and associated instability below the base of the lithosphere, and (3) plumes driven by deep-seated thermal instabilities. Wherever temperatures are higher than the solidus (b), water will be absorbed by partial melt. Any migration of this melt will leave a dried residual asthenosphere with anomalous melting temperature and mechanical properties. Conductive cooling at great age may be limited to a compositionally established depth or arrested by regulated convection in the asthenosphere (as shown by the plate-cooling geotherm in (c)). Properties such as seismic velocity (d) and viscosity (e) are likely

controlled by a combination of temperature, water content, and locally ponded partial melt. The zone of partial melt in the asthenosphere rising to supply material for crustal creation and lithospheric thickening has been discussed by Plank and Langmuir (1992) and others; the solidi (for dry and damp peridotite) are adopted from the summary of Asimow et al. (2004); the old ocean geotherm is computed using the temperature-dependent thermal conductivity structure summarized by Hasterok and Chapman (2011) including radiative heat transport (e.g., Hofmeister 1999) and an assumed radiogenic heat production rate of $0.5 \mu\text{W m}^{-3}$ in the oceanic crust; effects of sediment accumulation or crustal hydrothermal circulation are not included; velocity structure is adopted from surface wave tomographic results of Schaeffer and Lebedev (2013) with the localized low-velocity zone following results of Mehrouachi and Singh (2018); viscosity, based on Mitrovica and Forte (2004), is highly schematic and includes an anomalous zone corresponding to the seismic low-velocity layer

Lithosphere, Oceanic: Thermal Structure, Fig. 2 Oceanic heat flux. Data (from Hasterok et al. 2011) are plotted versus lithospheric age in (a) and versus age^{-1/2} in (b). Because raw heat flux data in young, sparsely sedimented areas are systematically biased by hydrothermal circulation, the data in these plots have been filtered to exclude sites where sediment thickness is less than 325 m and which are within 85 km of a known seamount. Data are drawn from all oceans. Solid dots show median heat

flux for 2 My age bins; gray shading is ± 1 standard deviation for the measurements in a bin. Open symbols represent high-quality data sets drawn from experiments where the environment of the heat flux sites is known from seismic imaging of the seafloor and other geophysical observations. The dashed and solid lines represent heat flux for half-space and plate cooling models, respectively

isostatic compensation, sediment loading, crustal thickness variations, and sub-lithospheric density anomalies. Early data compilations were made with only modest regard to these factors (e.g., Davis and Lister 1974; Parsons and Sclater 1977); later studies, such as those of Schroeder (1984), Marty and Cazenave (1989), Johnson and Carlson (1992), Hillier and Watts (2005), and Crosby et al. (2006), have put more effort into “filtering” data to define depth/age transects that are relatively free of the effects of known or suspected major mantle convective upwellings and downwellings, crustal thickness anomalies, and thick sediment accumulations. Despite the various potential sources of “noise” (which, as in the case of heat flux data, add bias, in this case typically causing observed depths to be anomalously shallow), all compilations have shown a similar result, with seafloor depths increasing proportionately with age^{1/2} until 70–80 Ma (Fig. 3b). Depths at greater ages fall off of this trend and generally stabilize at about 5.6 km. Other systematic behavior has been gleaned from the compilations, most notably that the rates of subsidence vary both locally and regionally and that the rate of subsidence is related to the depth of the local ridge axis (Davis and Lister 1974; Marty and Cazenave 1989; Hillier and Watts 2005; Crosby et al. 2006). This behavior is believed to reflect variations in the temperature of the asthenosphere supplying material at and near spreading centers (Klein and Langmuir 1987).

Depth of the Lithosphere-Asthenosphere Boundary

A third measureable indication of the thermal state of oceanic lithosphere is lithospheric thickness itself, identified principally by observations from seismology. Laboratory observations and field calibrations show that shear-wave velocity in mantle rocks is a strong function of temperature, with values decreasing rapidly (up to 0.1% K⁻¹) with approach to the melting temperature (Gibb and Cooper 1998; Priestley and McKenzie 2006). Hence, shear-wave velocities determined from dispersive surface waves provide a useful constraint on temperature at depth. An even greater influence derives from the presence of partial melt, which is controlled by temperature and the presence of water. Partial melt also reduces compressional wave velocity and electrical resistivity.

Surface wave data show a clear age-dependent structure for the uppermost mantle. A low-velocity zone is distributed widely in the oceans; it is thick and rises to the surface at mid-ocean ridges and extends beneath a high-velocity lid (the “seismic lithosphere”) that thickens with age out to roughly 70 Ma (Ritzwoller et al. 2004; Schaeffer and Lebedev 2013). Overall it centered at roughly 100 km. The long wavelength of surface waves poses a severe limitation on the depth resolution of the structure defined. This limit is being overcome by use of receiver function analyses permitted by a small but growing number of long-term broadband

Lithosphere, Oceanic: Thermal Structure, Fig. 3 Oceanic bathymetry. Data (from Hasterok et al. 2011) are plotted versus lithospheric age in (a) and versus age^{1/2} in (b). Bathymetry plotted is the position of the top of the igneous crust, 1-D isostatically adjusted for the effect of local

sediment loading. Solid dots are median values for 2 My bins of seafloor age; gray shading is ± 1 standard deviation for the measurements in a bin. Dashed and solid lines represent bathymetry for half-space and plate cooling models, respectively

seismometer deployments (e.g., Kawakatsu et al. 2009), by analysis of SS waveforms that contain a reflection from the base of the lithosphere (Rychert and Shearer 2011), and by active-source seismic reflection data where recording has been extended to several tens of seconds (e.g., Stern et al. 2015; Mehouchi and Singh 2018). Observations made using these methods, particularly the last, require a relatively sharp lower boundary to the lithosphere and a thin zone hosting partial melt beneath (although this inference has been debated; e.g., Olugboji et al. 2016; Niu and Green 2018). Magnetotelluric data also strongly suggest the presence of partial melt at the base of the lithosphere, distributed in a way that is sufficiently interconnected to cause anomalously high electrical conductivity with a bias in the direction of plate motion (e.g., Naif et al. 2013).

Depths to the base of the lithosphere defined using these various techniques vary significantly, with a systematic difference between those estimated from shear-wave dispersion observations (gray symbols in Fig. 4) and those determined from seismic reflections and other techniques (black symbols). Both groups, however, suggest an age dependence of lithospheric thickness in younger settings and stabilization in older settings. All methods show great promise; additional studies will be needed to define just how consistent or variable the relationship between lithospheric thickness and age might be and to determine whether seismic reflections define the thickness of the lithosphere more accurately than surface wave dispersion.

Other Observational Constraints

Additional constraints on lithospheric thermal structure are provided by observations of flexural rigidity, gravity, and geoid. Gravity data provide little information about the very long-wavelength signature of lithospheric cooling except to confirm that the topography is isostatic. At the shorter wavelengths of abyssal hills, seamounts, and swells, gravity is sensitive to the vertical mass distribution and can be used to discriminate whether topography is supported or unsupported by lithospheric strength and to constrain the depth of compensation of isostatic topography (e.g., Watts 2007; Crosby and McKenzie 2009). The geoid is sensitive to long-wavelength density structure and provides a useful constraint on the thermally influenced density of oceanic lithosphere. A linear relationship between geoid height and age is seen over young seafloor, with a proportionality ranging between 0.1 and 0.14 m Myr⁻¹, whereas the response is flat at ages greater than 80 Ma (e.g., Haxby and Turcotte 1978; Sandwell and Schubert 1980; De Laughter et al. 1999).

Flexural rigidity (usually expressed as effective elastic thickness) and ultimate strength are strongly controlled by temperature. The first of these related properties is reflected by the long-term load-bearing capacity and is determined using the wavelength of flexure and the relationship between gravity and topography in the vicinity of large seamounts, trenches, fracture zones, and other crustal or tectonic loads. As in the case of the thickness of the high shear-wave-velocity lid, a clear age dependence has been revealed that shows that

Lithosphere, Oceanic: Thermal Structure, Fig. 4 Oceanic lithosphere thickness measured as the depth to the seismic low-velocity zone. Data, primarily from the Pacific Basin, are plotted versus lithospheric age in (a) and versus age^{1/2} in (b). Symbols indicate types of analysis and uncertainties: gray symbols indicate estimates derived from surface wave dispersion (Leeds et al. 1974, Leeds 1975, crosses; Burgos et al. 2014, squares); black crosses are from receiver function analyses

(Kawakatsu et al. 2009 and Olugboji et al. 2016); black x's are from SS precursor analysis (Rychert and Shearer 2011); inverted triangles are from active-source seismic reflection profiling (Mehouachi and Singh 2018); and the red diamond is from magnetotelluric data analysis (Naif et al. 2013). The dashed line shows the rate of thickening expected for half-space cooling

the effective elastic thickness is limited by temperature, although the scatter in thicknesses and inferred maximum temperatures is large, with the latter falling between 200 and 600 °C. This reflects in part the dependence of this property on the duration of loading.

A limiting constraint on ultimate strength is provided by the occurrence of earthquakes, and when placed in a context of age, a relationship is also seen. The maximum depth of hypocenters increases with increasing age, and the limiting temperatures for seismogenic failure falls at roughly 600 °C (McKenzie et al. 2005). Again, the rate of loading that leads to seismogenic failure is an important factor (in addition to temperature) controlling this property. Settings in which deep earthquakes occur are normally complex (such as in subduction zones), however, and this restricts the quantitative utility of the depth distribution of earthquakes for defining the thermal structure of the lithosphere.

Ways of Understanding Lithospheric Thermal Structure

Because the lithosphere is not in an equilibrium state in most oceanic regions, the local thermal structure cannot be defined directly from seafloor heat flux, subsidence, or other observations. It must be estimated using transient cooling models, constrained by the observations described above along with estimates of material properties at depth.

Boundary-Layer Cooling

The simplest physical description of the thermal structure of oceanic lithosphere is provided by boundary-layer cooling theory (Parker and Oldenberg 1973; Davis and Lister 1974). Except very near the ridge axis, cooling is vertical and equivalent to cooling of an initially uniform-temperature half space. The lithosphere is defined simply as cooled asthenosphere with the boundary defined by an isotherm that deepens with age and thus distance from the ridge. Heat flux through the seafloor, Q , decreases with age, t , as $Q = \lambda T_a (\pi \kappa t)^{-1/2}$, and seafloor depth, h , increases as $h = 2 \alpha_{eff} T_a (\kappa t / \pi)^{1/2}$, where T_a = the initial temperature of the asthenospheric material from which the lithosphere forms (relative to seawater at $T \approx 0$ °C), κ = thermal diffusivity, $\alpha_{eff} = \alpha \rho_0 / (\rho_a - \rho_w)$ is the effective volumetric thermal expansivity adjusted for seawater loading, and ρ_a and ρ_w are the densities of the asthenosphere and seawater, respectively. The thermal properties are known to be sensitive to temperature (e.g., Hofmeister 1999); this dependence must be considered when estimating temperatures at depth (e.g., McKenzie et al. 2005), but it does not change the simple predicted dependence of subsidence and heat flux on age. The simplest application of boundary-layer cooling theory produces a heat flux singularity at the ridge axis; this is dealt with by applying a heat-balance boundary condition at the ridge axis (Davis and Lister 1974). Two important predictions of the theory are that the heat flux integrated from $t = 0$ to $t = a$ is $2 Q(a)$, and that the heat flux is related to seafloor depth as $Q = (\rho c_p / \alpha_{eff}) dh/dt$,

where c_p is the specific heat at constant pressure and α_{eff} is appropriate for 0.7 of T_a (Lister 1977). Wherever cooling follows boundary-layer behavior, this relationship can be used to obtain a robust estimate of the heat loss from the oceanic lithosphere without a need for relying on sparse, scattered, and potentially biased seafloor heat flux data.

When plotted as functions of $t^{-1/2}$ and $t^{1/2}$ as they are in Figs. 2b and 3b and considered in light of the heat flux/subsidence relationship given above, the heat flux and depth observations clearly demonstrate the efficacy of boundary-layer cooling theory for characterizing lithosphere younger than 70–80 Ma. The same is true for the geoid, which is predicted by boundary-layer cooling theory to decline at a rate of 0.16 m Myr^{-1} (Haxby and Turcotte 1978), and for the thickening of the lithosphere itself, which (as defined by seismic surface wave dispersion analysis) occurs at a rate of roughly $11 \text{ km Ma}^{-1/2}$ (Fig. 4b). The cessation of simple subsidence, the flattening of the geoid, and the stabilization of the lithosphere/asthenosphere boundary depth beyond about 70 Ma, as well as the relatively constant heat flux beyond an age of roughly 100 Ma, all require something more complex than heat loss via transient cooling, however.

Plate Cooling Models

That ocean depths at great ages are relatively uniform and consistently shallower than those predicted by boundary-layer cooling provided the fundamental rationale for plate cooling models, which describe the lithosphere as a layer of constant thickness having a fixed lower boundary temperature (McKenzie 1967). This description was initially used out of mathematical convenience. There was little physical justification for the lithosphere to have an intrinsic thickness, or for constant heat flux to be supplied by asthenospheric convection beneath old lithosphere, until physical arguments were made for the latter by Parsons and McKenzie (1978) by way of an age-dependent onset of convection in the growing thermal boundary layer below the cooled, mechanically immobile lithosphere. Physical modeling of convection using material having a strongly temperature-dependent viscosity has shown how this phenomenon can serve to stop and possibly even reverse subsidence and later stop the decline in heat flux with age (Davaille and Jaupart 1994; Crosby et al. 2006). The key factor in this model is the growth of the thermal boundary layer beneath the conductively cooled plate. Once this layer reaches a sufficient thickness to become convectively unstable, convection begins to bring heat advectively from the large reservoir of the asthenosphere beneath. A balance is ultimately reached between the heat conducted through the lithosphere and that carried by convection in the asthenosphere.

Alternate means suggested for maintaining an effectively steady-state lithosphere at great age include convection driven from below (plumes, distributed radiogenic heat, and

secular cooling) and creation near ridge axes of a compositionally distinct layer (Oxburgh and Parmentier 1977; Morgan 1997). The first by itself is precluded as a general case by both topographic and heat flux observations which show no statistically significant influence of augmented heat flux at intermediate ages where the evolution of the lithosphere is well matched by boundary-layer cooling theory. Regulated heat flux by asthenospheric convection is also argued against by the contrast between heat flux at the base of the lithosphere beneath old oceanic and old continental regions, the latter being less than half of the former. The second seems unlikely in light of the observations of seismic reflections at the base of the lithosphere (e.g., Fig. 4), which suggest that there is a weak layer at the lithosphere-asthenosphere boundary (depicted schematically in Fig. 1e). Any compositional differences resulting from the extraction of partial melt and water from the asthenosphere in the source zone for the oceanic crust (e.g., Plank and Langmuir 1992; Asimow and Langmuir 2003; see Fig. 1a) must be concentrated in a volume near the ridge axis and not carried laterally for lithospheric underplating at greater age. The effects of composition and water content must not to be discounted in terms of their influence on viscosity and melting temperature, however (e.g., Hirth and Kohlstedt 1996; Asimow and Langmuir 2003; Asimow et al. 2004). Preconditioning via partial melt of the asthenosphere from which the lithosphere is created may happen wherever asthenospheric ascent occurs to replace material lost to the thickening and laterally migrating lithosphere.

Influence of Plumes

Convective plumes in the asthenosphere, with defining characteristics of localized upwelling and anomalously high temperatures (possibly more than 200 K higher than typical asthenospheric temperatures; Putirka 2005), have been argued to thin or “reset” the thermal age of oceanic lithosphere (see review in Detrick et al. 1989), with the eventual collective contribution from plumes resulting in the departure from boundary-layer cooling behavior (Heestand and Crough 1981) and possibly in the supply of much of the heat flux to the base of plates (Malamud and Turcotte 1999), although these possibilities remain controversial. Locally the influence of plumes can certainly be large; surface volcanism from plumes is typically highly focused, but the associated topographic swells are large and extensive, often exceeding 1 km in amplitude and having a wavelength approaching 1000 km. A similarly broad thermal anomaly is implied for a source of the swells, but given the large thermal time constant of the lithosphere, seafloor heat flux provides an inherently poor constraint on the depth of the thermal source; attempts have been made to infer anomalies at depth with understandably mixed results (e.g., Von Herzen et al. 1989). A study of the geoid signature over the Hawaiian Swell by Moore and

Schubert (1997) suggests that the lower part of the lithosphere is involved, but a study of the topography and gravity over swells by Crosby and McKenzie (2009) reveals an admittance (30 mGal km^{-1}) that is consistent with the thermal density anomaly being below the base of the plate.

Driving Forces for Lithospheric Motion

An element that is essential to a complete description of oceanic plates is the source of the force that drives their motion. Great attention has been given to the subject of plate driving forces ever since the formulation of the concept of plate tectonics (McKenzie 1969; Forsyth and Uyeda 1975; Runcorn 1980; Richardson 1992). Possible forces considered have been traction from large-scale convection at the base of the lithosphere (both oceanic and continental), negative buoyancy at subduction zones, and gravitational sliding away from mid-ocean ridges. Drive from basal traction forces is probably insignificant. Convection in the asthenosphere is generally too small in scale and directionally random, outside of the general flow required to maintain a mass balance between lithospheric creation at ridges and destruction at subduction zones which would generate a bias in the wrong direction. In addition, the low seismic shear velocity, high electrical conductivity, and possible presence of melt (Fig. 1) suggest that the lithosphere is mechanically decoupled from the asthenosphere. Such decoupling reduces any force transfer at the base of the asthenosphere, including near mid-ocean ridges where there could be a potential for “ridge push.”

Most of the driving force for plate tectonics probably arises from the lithosphere itself, specifically the thermally derived density contrast between the lithosphere and asthenosphere. Wherever boundary-layer cooling governs the thickness of the lithosphere (i.e., where plate age is less than 70–80 Ma), gravitational forces associated with the thermally elevated lithosphere drive it down along its sloping lower boundary. This results in a body force that is constant with age (e.g., Lister 1975). The greatest role the lithosphere plays in moving itself is believed to occur at subduction zones, where cooled oceanic lithosphere sinks into the asthenosphere. The dominance of this negative buoyancy force is apparent in the global variations of plate velocities: plates bounded by subduction zones that are lengthy and consume old oceanic lithosphere, specifically the Pacific and Australian/Indian plates, move at the fastest rates. The negative buoyancy of subducting plates also provides the force for the genesis of mountain belts.

Summary

A broad suite of observations gathered in context of powerful physical models have brought plate tectonics from a largely

geometrical description of the history of the surface of the Earth to a robust theory that explains many geological processes. Among other things, this theory addresses the mechanisms by which plates form and are driven, the thermal structure of oceanic lithosphere that influences its mechanical and geodynamic behavior, and the dominant modes of heat loss from the Earth. In particular, the mathematics of half-space cooling – applied to the physical model of seafloor spreading and constrained by carefully considered observations – leads to simple but profound approximations for the heat loss, bathymetry, and lithospheric thickness in young ($< 70\text{--}80 \text{ Ma}$) oceanic regions of the Earth and suggests the following relationships for predicting heat flow through the seafloor (Q , in mW m^{-2}), depth below sea level of the seafloor (d , in km), and depth below seafloor of the lithosphere-asthenosphere boundary (l , in km) as functions of age (t , in My):

$$\begin{aligned} Q &= 500t^{-1/2} \\ d &= 2.6 + 0.34t^{1/2} \\ l &= 11t^{1/2} \end{aligned}$$

Departures from these relationships occur in regions of anomalous upper mantle temperatures and in regions of greater age, but with modifications for seafloor greater than 80 My to account for the limits of conductive cooling, these simple approximations explain heat flow, bathymetry (thermal subsidence), and lithosphere thickness for more than two thirds of the Earth's surface.

Uncertainties remain, however, and further work is required to resolve several lingering questions about lithospheric creation, cooling, and eventual stabilization. Among these are (1) to what degree is the mechanical behavior of oceanic lithosphere (particularly its resistance to thinning by convection of any form in the asthenosphere) established compositionally by the extraction of partial melt and water at ridge axes or in young regions; (2) to what degree does asthenospheric convection stimulated by top-down cooling regulate heat loss through and limit the growth of the lithosphere at great age; and (3) to what degree do plumes, the consequence of convective instabilities generated deep in the asthenosphere, contribute to heat flux at the base of plates, and do they convectively thin or merely conductively warm the plates beneath which they ascend? Addressing the first will improve constraints on plate drive generated by gravitational sliding forces, which are maximum for the case of a mechanical lithosphere being defined purely as a cooling boundary layer. Addressing the second and third will help resolve just what the primary regulating factor is that constrains the rate of heat loss from the Earth, such as the form and vigor of asthenospheric convection, the quotient of asthenospheric temperature and lithospheric thickness, or the rate of

production and destruction of lithosphere at ridges and subduction zones.

It is noteworthy that in addressing the primary topic of this chapter, the thermal structure of the oceanic lithosphere, we have had to lean heavily on indirect constraints. Even with the help of boundary-layer and plate cooling models, uncertainties of the parameters required for estimating deep lithospheric thermal structure from seafloor heat flux – specifically thermal conductivity, heat capacity, and heat production rate – lead to equivalent uncertainties in estimates of temperatures at depth. For this reason we have chosen to integrate other observations that constrain temperatures, as reflected in Figs. 1 and 4, and we urge readers to accept any estimates of deep temperatures with suitable caution.

Crustal (magnetic) field; Lithospheric (magnetic) field

Definition

Geomagnetic field is Earth's magnetic field. Units are nT (nanoTesla). The geomagnetic field at the Earth's surface has a magnitude of 25,000 nT to 65,000 nT. *LEO satellites* are spacecraft orbiting above Earth's surface with an altitude of less than 2000 km. Typical altitudes of satellites measuring Earth's magnetic field are between 300 km and 700 km. *Magnetic observatories* are land-based stations collecting measurements of Earth's magnetic field. Magnetic observatories collect absolute measurements in contrast to variometer stations which measure magnetic field variations. *Geomagnetic storms* are perturbations in the Earth's magnetic field caused by temporary disturbances of Earth's magnetosphere usually caused by fluctuations in the stream of charged particles originating from the sun known as the solar wind. *Space weather* refers to the electromagnetic conditions in Earth's space environment such as in the solar wind and within the magnetosphere and ionosphere.

Introduction

The Earth possesses a rich magnetic field generated mainly by the motion of conducting metals, mostly molten iron and nickel, in our planet's liquid (outer) core. The liquid core is found in a layer between ~2900 km and ~5150 km (Busse

2011) deep inside Earth. This self-sustaining process which maintains Earth's magnetic field is known as the geodynamo and produces a field with a strength of 25,000 nT near the equator and 65,000 nT near the poles making up about 95% of Earth's total magnetic field. The remaining few percent is produced by magnetized material in the Earth's lithosphere as well as by electric currents in the ionosphere at about 90 km to 1000 km altitude and magnetosphere, which extends to distances larger than several thousands of km, creating fields ranging from a few nT to thousands of nT at polar latitudes (Olsen and Stolle 2012). And lastly, a very small fraction is produced by induced electric currents in the Earth's mantle, lithosphere, and ocean creating fields of a few nT.

The Earth's crust and the underlying uppermost part of the mantle make up the lithosphere which is about 100 km thick (Langel and Hinze 1998). The lithospheric magnetic field exhibits high regional variability because it depends on the local geological history, petrochemical composition, and physical properties of the magnetized rocks of the region. It can locally reach magnitudes of several hundreds or even thousands of nT, and since it is a small fraction of Earth's total field, it is often referred to as the anomaly field and the associated magnetic signatures of the magnetized rocks are the lithospheric magnetic anomalies. Therefore, to determine the lithospheric field globally, detailed magnetic field observations with global coverage are needed. Low Earth Orbiting (LEO) satellites provide the most effective means of acquiring such observations and provide efficient coverage for the determination of Earth's lithospheric field on a global scale. As an example, Fig. 1 shows the global distribution of magnetic ground observatories (red dots) collecting measurements of Earth's magnetic field versus the measurements taken along a satellite orbit during 24 h (yellow ground track). It is clear that the present ground observatory network provides a sparse data distribution compared to the spatial coverage (even from only 24 h) of satellite observations. Continuous satellite data for several months or even years provide a dense net of magnetic field observations far superior to what is possible with observations close to Earth's surface. However, due to orbital mechanics, the orbits of LEO satellites used in geomagnetism are usually inclined, that is, the angle between the orbit plane and the equatorial plane is not exactly 90° (it is usually $\sim 90^\circ \pm 3^\circ$ to 6°), which results in leaving a small cap around the two geographic poles unsampled (see polar views on Fig. 1). These unsampled regions are known as "polar gaps."

The Lithospheric Field from Space

An extensive review of measuring the Earth's lithospheric field with satellites is given by Langel and Hinze (1998) from the Polar Orbiting Geophysical Observatories (POGO) launched between 1965 and 1971, until the Ørsted satellite

which was launched in 1999. POGO were the first satellites to provide global measurements of the Earth's magnetic field whereas Ørsted marked the start of the International Decade of Geopotential research, an international effort to promote and coordinate a continuous monitoring of the geopotential (magnetic and gravity) field variability in the near-Earth environment. Two missions followed after the launch of Ørsted which provided the most detailed data for lithospheric field modeling and enhanced our knowledge of the global contour of Earth's magnetized lithosphere. The first mission, CHAMP, was launched in 2003 and the second one, called Swarm, was launched in 2013. Ørsted, CHAMP, and Swarm have provided continuous measurements with an extended time-space coverage that helped improve our ability to characterize and understand the various sources that contribute to Earth's magnetic field. Currently, Swarm is the only operational mission dedicated to measuring Earth's magnetic field. It is a constellation of three identical satellites two of which are separated by ~ 150 km (at the equator and < 150 km in higher latitudes) in the east-west direction and orbit as a pair at lower altitudes (≤ 460 km) and a third flying at higher altitude (≤ 530 km) sampling different local times than the lower pair. The Swarm satellite mission provides a new dimension of detecting lithospheric anomalies from space. By using simultaneous (or near-simultaneous) measurements from the lower satellite pair, cross-track gradients (which approximate east-west gradients at nonpolar latitudes) of the magnetic field can be estimated. Gradients suppress the signals from external sources and specifically amplify the small-scale lithospheric anomalies. A full basis of magnetic space gradiometry, that is, the measurement of magnetic field gradients from satellites, and their advantages in the lithospheric field exploration is given by Kotsiaros and Olsen (2012). Specifically, east-west gradients contain valuable information on North-South oriented features of the lithospheric anomalies. Similarly, information on east-west features requires knowledge of the North-South gradient. North-South gradients can be approximated by along-track gradients (at nonpolar latitudes) which in turn can be estimated by finite differences along the satellite's track. However, on the contrary to cross-track gradients, along-track gradients are not instantaneous since they are estimated from measurements from a single satellite taken at different time instances. Therefore, the spacing of the along-track finite differences is important for maximizing the signal to noise ratio. Kotsiaros et al. (2015) has shown the optimal estimation of along-track gradients and their added benefit for lithospheric anomaly detection using data from the CHAMP mission.

Figure 2 shows how lithospheric anomalies are seen by (a) vector data (the radial component B_r) (b) across-track $\left(\frac{dB}{d\phi}\right)$, and (c) along-track $\left(\frac{dB}{d\theta}\right)$ gradients. While across-track gradients amplify north-south structures, along-track gradients amplify

Lithospheric Magnetic Anomalies from Satellite Data,

east-west structures. Evidently, both gradients contain additional information and show anomalies with a higher level of detail compared to vector data.

In general, both the magnitude and spatial scale of the lithospheric anomaly signals are attenuated at satellite altitude. The process of propagating the measured anomaly signals from satellite altitude down to the Earth's surface is called downward continuation. Although downward continuation is a very useful tool for estimating the magnetic field at the Earth's surface, systematic errors are also propagated and amplified together with the signal. This creates artifacts in the mapping of lithospheric anomalies.

Mathematical Background

The magnetic field measured by a satellite is a superposition of contributions from various sources and their separation based on magnetic field measurements is challenging. The

lithospheric magnetic field signal is therefore entangled with the signals originating from the Earth's core, ionosphere, and magnetosphere. The first attempt to separate the various magnetic field contributions was performed more than 100 years ago by Gauss (1877) (a revised translation from the German text is provided by Glassmeier and Tsurutani (2014)). Gauss introduced the concept of spherical harmonic analysis and the various sources can be separated based on the fact that each of their contributions has a specific spatial and temporal characteristic.

For example, with Earth's surface as reference, the magnetic field sources can be separated into "internal" originating in the Earth's core and lithosphere and "external" originating in the ionosphere and magnetosphere. The magnetic field due to internal sources varies as a function of $(\frac{a}{r})$, with $a = 6371.2$ km (the mean Earth's radius) and $r > a$ the radial distance of the measurement location, whereas the field due to external sources varies as a function of $\sim(\frac{r}{a})$.

Lithospheric Magnetic Anomalies from Satellite Data, Fig. 2 Lithospheric anomalies at satellite altitude (450 km) detected by (a) vector data (radial component, B_r), (b) across-track $\left(\frac{dB}{d\phi}\right)$, and (c) along-track $\left(\frac{dB}{d\theta}\right)$ gradients

In regions without electric currents, such as along most part of the satellite orbits, the magnetic field, $\mathbf{B}$, can be written as the (negative) gradient of a scalar potential V ,

$$\mathbf{B} = -\nabla V \quad (1)$$

and because of $\nabla \cdot \mathbf{B} = 0$, the potential V has to obey Laplace's equation: $\nabla^2 V = 0$. The scalar potential V can be split into an internal part V^{int} and an external part V^{ext} , which correspond to the internal and external magnetic field sources, that is,

$$V = V^{\text{int}} + V^{\text{ext}} \quad (2)$$

and from Eq. (1) we have:

$$\mathbf{B} = -\nabla V^{\text{int}} - \nabla V^{\text{ext}} = \mathbf{B}^{\text{int}} + \mathbf{B}^{\text{ext}}. \quad (3)$$

The internal and external potentials V^{int} and V^{ext} can be expanded in series of spherical harmonics (which are solutions of Laplace's equation):

$$V^{\text{int}} = a \sum_{n=1}^{N^{\text{int}}} \sum_{m=0}^n \times (g_n^m \cos m\phi + h_n^m \sin m\phi) \left(\frac{a}{r}\right)^{n+1} P_n^m(\cos \theta) \quad (4)$$

$$V^{\text{ext}} = a \sum_{n=1}^{N^{\text{ext}}} \sum_{m=0}^n \times (q_n^m \cos m\phi + s_n^m \sin m\phi) \left(\frac{r}{a}\right)^n P_n^m(\cos \theta), \quad (5)$$

where $a = 6371.2$ km is the Earth's mean radius, (r, θ, ϕ) are geocentric spherical coordinates, $P_n^m(\cos \theta)$ are the associated Schmidt semi-normalized Legendre functions of degree n and order m , and g_n^m , h_n^m and q_n^m , s_n^m are the spherical harmonic expansion coefficients describing the internal and external sources respectively. For more details see Chapman and Bartels (1940) and Langel (1987). Theoretically, the series extend up to infinite degree, but since in practice there is only a limited number of measurements at discrete points, the series are truncated at a maximum degree N^{int} (N^{ext}) for the expansion of the internal (external) potential. The estimation of the internal (or external) spherical harmonic coefficients g_n^m , h_n^m (or q_n^m , s_n^m) from discrete satellite measurements of $\mathbf{B}$ is known as spherical harmonic analysis and the set of the estimated coefficients is referred to as a (global) magnetic field model. From the estimated spherical harmonic coefficients (the model), we can calculate the magnetic field values $\mathbf{B}$ at any given point. This process is called spherical harmonic synthesis. LEO satellites that measure Earth's magnetic field orbit above the highly conducting layer of the ionosphere where the ionospheric currents flow (at about 110 km altitude) therefore they see the ionospheric field as an "internal" field. The separation of the lithospheric and ionospheric fields is challenging since both sources are internal to satellite observations. Therefore, lithospheric magnetic anomalies are often contaminated by ionospheric field signals in the satellite data. A standard technique to reduce contamination is to perform data selection and choose night time data when the conductivity of the ionosphere is low and the associated ionospheric magnetic field is significantly weak. An alternative, but also more complicated approach is to model the ionospheric magnetic field

simultaneously to the lithospheric field, an approach commonly known as comprehensive modeling (e.g., Sabaka et al. 2004). Another difficulty is the amalgamation of the lithospheric field with that originating in the Earth's core. Specifically, at spatial scales of ~ 3000 km the core field overlaps the lithospheric field making the derivation of separate high-quality magnetic models for the core and lithosphere at those spatial scales very challenging. Various techniques for modeling the lithospheric field are reviewed by Thébault et al. (2010).

Global Models of Lithospheric Magnetic Anomalies

Global models of the Earth's magnetic field were derived from satellite observations more than 50 years ago using measurement of the field intensity. However, intensity measurements alone do not provide enough information to derive unique global models and vector observations are required. The CHAMP mission has provided high-quality vector data with increased sensitivity to Earth's lithospheric field due to CHAMP's low altitude (< 350 km) during the last 4 years of its mission. Detailed models able to capture lithospheric magnetic anomalies at spatial scales of ~ 300 km, corresponding to spherical harmonic degree 133, were derived using CHAMP data (e.g., Maus 2010). However, Swarm significantly improved the lithospheric field mapping from space. Models derived from Swarm data are able to capture anomalies at spatial scales ~ 216 km, corresponding to spherical harmonic degree 185 (e.g., Olsen et al. 2017). Despite the present higher

altitude (~ 450 km) of Swarm compared to CHAMP and therefore its lower sensitivity to the lithospheric magnetic anomalies, this resolution enhancement is possible mainly due to the east-west gradient information provided by the unique Swarm constellation. Upcoming Swarm data taken at lower altitudes will further increase the resolution of global lithospheric field models. Figure 3 shows the global lithospheric magnetic field (radial component) based on a model derived exclusively from Swarm data (Olsen et al. 2017). Earth's lithospheric anomalies are stronger on the continental regions where the lithosphere is thick and weaker in the oceanic regions where it is thin. A strong anomaly in central Africa, known as the Bangui anomaly, stands out. The exact origin of the Bangui anomaly remains unclear, although two theories have been suggested. One proposes a large igneous intrusion and the other a meteorite impact. The largest magnetic anomaly on Earth in south-west of Russia, known as the Kursk anomaly, is associated with massive iron-ore formations in this region.

Earth is not the only planet in our solar system that bears a lithospheric magnetic field. In fact, Mars has a very interesting lithospheric field. The Martian lithospheric anomalies are primarily concentrated in the southern hemisphere and are ~ 10 times stronger than Earth's lithospheric anomalies. The Martian lithospheric field is the best surveyed planetary lithospheric field from space after Earth's. Mars Global Surveyor (MGS), which was in orbit around the red planet during 1997–2006, and Mars Atmosphere and Volatile Evolution (MAVEN), which was launched in 2013 and is still in orbit, have acquired accurate magnetic field observations which are sufficient to derive detailed global models of the Martian

Lithospheric Magnetic Anomalies from Satellite Data, Fig. 3 Earth's lithospheric magnetic anomalies determined by satellite data

Lithospheric Magnetic Anomalies from Satellite Data, Fig. 4 Mars' lithospheric magnetic anomalies determined by satellite data

lithospheric field. Figure 4 shows the magnetic anomalies of the Martian lithosphere based on a model derived from MGS data. The peculiarity of the Martian lithospheric anomalies gathered in the southern hemisphere is evident. The source of the anomalies is either large volumes of magnetized material, very strong remanence, or both.

Summary

Continuous high-precision magnetic field observations taken by satellites have enabled us to make considerable progress in the study of the magnetization of Earth's lithosphere. In particular, the capability of Swarm satellites to estimate magnetic field gradients has provided the means for mapping Earth's lithospheric magnetic anomalies from space with remarkable detail. The Swarm mission is foreseen to carry on surveying Earth's magnetic field at least until the end of 2021 and possibly for several years after that. However, presently, there is no mission planned to continue the geomagnetic field exploration from space after Swarm.

Uninterrupted observations of the magnetic field are important in order to capture the temporal evolution of the field generated in the Earth's liquid core as well as to separate the different magnetic field sources. The separation of the sources is done physically with the help of data selection and mathematically with the help of spherical harmonic series based on the different temporal and spatial characteristics of

the internal and external field contributions. A significant challenge still remains at those spatial scales where the lithospheric field overlaps with the core field. A proper full separation of the core and lithospheric field could perhaps be achieved if knowledge of the full geological history and in-depth chemical composition of Earth's lithosphere was known which is of course unrealistic on a global scale and perhaps even on a local scale.

Satellite observations provide excellent spatial data coverage making it possible to derive global models of Earth's magnetic field. However, the worldwide network of magnetic observatories is providing magnetic measurements that are equally important despite their inferior spatial coverage compared to satellites. For example, data from magnetic observatories are used to derive indices which characterize Earth's external field activity and describe space weather related events such as geomagnetic storms. Data from magnetic observatories can be used to complement satellite data for modeling Earth's magnetic field.

Magnetic Anisotropy

Leonardo Sagnotti

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

Definition

The magnetic properties of rocks and minerals are generally anisotropic, that is, they are directionally dependent. Magnetic anisotropy of minerals arises either from fundamental anisotropy in the crystal structure or from the shape of non-spherical ferromagnetic grains. The most common cause of magnetic anisotropy in rocks is the preferential distribution-orientation of the constituting minerals, in other words the rock fabric.

Introduction

Pioneering works on the magnetic anisotropy of rocks were carried out during the 1940s and 1950s (Ising 1942; Graham 1954). These authors first realized that magnetic methods may be used to characterize the preferred orientation of minerals within the rock samples. Ising studied varved clays in Sweden and noticed that the magnetic susceptibility was higher on the bedding plane than orthogonally to it. Graham recognized that the anisotropy of magnetic susceptibility may be regarded as a petrofabric element; he later extended the analysis to various sedimentary rocks of the Appalachian Mountains and pointed out the existence of distinct and systematic relationships of the magnetic fabric with structural setting (Graham 1966). The studies progressively developed in the following decades, and a first comprehensive review on magnetic anisotropy and its application in geology and geophysics was published by Hrouda (1982). Researches on magnetic anisotropy then gained widespread use and were extended to examine the fabric in a variety of sedimentary, igneous, and

metamorphic rocks (e.g., see reviews by Jackson 1991; Rochette et al. 1992; Tarling and Hrouda 1993; Borradaile and Jackson 2010; Parés 2015; Bilardello 2016). Presently, the study of the magnetic anisotropy of rocks is still one of the most promising research issues in the field of rock magnetism.

Theoretical Principles

Two principal mechanisms control the magnetic anisotropy of rocks: (1) lattice alignment of crystals with magnetocrystalline anisotropy and (2) shape alignment of ferromagnetic grains.

Magnetocrystalline Anisotropy

This is an intrinsic property of all minerals since it arises from the ordered structure of elementary particles in the crystal lattice; it is defined as the energy per atom needed to move the crystal magnetization from one crystallographic direction to another. Magnetocrystalline anisotropy thus reflects the dependence of the free energy of a magnetic system on the direction of magnetization. In the atomic structure of a crystal, the spin-orbit coupling between the magnetic spins and the lattice establish “easy” and “hard” directions of magnetization and determine the orientation of the spin moments with respect to the crystal structure. Within ferromagnetic crystals (the term ferromagnetic will be used in the following in its broader sense, that is, to indicate all minerals with ordered magnetic spin structures, including ferrimagnetic and antiferromagnetic ordering), the exchange energy in the $3d$ electronic orbitals of transition elements (e.g., Fe, Co, Ni) is, unlike the s orbitals, anisotropic. Hence, within these crystals, electron spins will be easier to coordinate in some directions than in others. Along these directions, the elemental electron spins align more readily, and the magnetization acquired in an applied field is greatest. In magnetite the direction of the lowest magnetocrystalline anisotropy energy (i.e., the easy axis of magnetization) is along the body diagonal, that

is, the [111] crystallographic direction. In hematite, magnetocrystalline anisotropy is very weak in the basal plane, but it is very high along the crystallographic c -axis, perpendicular to this plane. Consequently, hematite crystals may be easily magnetized by magnetic fields applied along the basal plane and are almost unaffected by fields applied perpendicular to it.

Shape Anisotropy

Shape anisotropy mostly occurs in ferromagnetic minerals with high intrinsic susceptibility and low degree of magnetocrystalline anisotropy (e.g., magnetite, maghemite), where just a slight deviation from the isometric shape produces notable magnetic anisotropies, in order to minimize the magnetostatic energy due to the formation of surface magnetic poles at the extremities of the mineral grains. In ferromagnetic minerals, the alignment of electron spins produced by exchange energy or by the application of an external magnetic field generates an external magnetic field that is proportional to the spontaneous or induced magnetic moment and may be represented as a field produced by an apparent distribution of north and south magnetic poles on the surface of the crystal. In turn, the surface magnetic poles generate an internal field whose field lines start on the north magnetic poles on the surface and end on the south poles (Fig. 1). This internal field is, therefore, antiparallel to the alignment of the magnetic moments within the crystal, and it is known as the demagnetizing field $\mathbf{H}_d$. Such a demagnetizing field is proportional to the magnetization $\mathbf{M}$ of the crystal and is sensitive to its shape:

$$\mathbf{H}_d = -N\mathbf{M}$$

where N is a demagnetizing factor which is determined by the shape of each crystal.

Shape anisotropy arises from the dependence of the demagnetization factor N on the direction of magnetization with respect to the particle shape. Different directions of magnetization results in different arrays of surface poles. N is a tensor depending on the grain shape: for a spherical grain, $N = 1/3$; for an ellipsoid grain with principal axes $a \geq b \geq c$, $N_a + N_b + N_c = 1$.

Magnetic Anisotropy, Fig. 1 Surface magnetic poles and internal demagnetizing field $\mathbf{H}_d$ for an ellipsoidal grain with uniform axial magnetization $\mathbf{M}$

By analogy with electrostatics, magnetostatic forces decrease with distance, and the internal demagnetizing field is reduced when the surface poles are furthest apart. In the case of an ellipsoid magnetized parallel to the elongation axis a , the demagnetizing field, which depends on $1/r^2$, is weaker than in the case of a sphere (i.e., $N_a < 1/3$). Similarly, if the ellipsoid is magnetized along the shortest axis c , the demagnetizing field is stronger (i.e., $N_c > 1/3$). In general, the demagnetizing factor N is minimum for very elongated (“pencil shape”) grains and maximum for platy grains (“disc shape”). In an ellipsoid of revolution, N_a approaches 0 for an infinite needle ($N_b = N_c = 1/2$), and N_c approaches 1 for a disc of infinite thinness ($N_a = N_b = 0$).

The demagnetizing factor N determines the intensity of the magnetic field that effectively acts ($\mathbf{H}_{\text{eff}}$) within a grain subjected to an external applied field $\mathbf{H}_{\text{ex}}$:

$$\mathbf{H}_{\text{eff}} = \mathbf{H}_{\text{ex}} - N\mathbf{M}$$

The magnetization $\mathbf{M}_j$ of a grain along an arbitrary direction j is given by

$$\mathbf{M}_j = k_o \mathbf{H}_{\text{ex}} = k_i \mathbf{H}_{\text{eff}} = k_i (\mathbf{H}_{\text{ex}} - N_j \mathbf{M}_j)$$

where k_o is the observed magnetic susceptibility along the direction j ; k_i is the intrinsic magnetic susceptibility of the grain, which is isotropic and dependent only on the chemical composition of the mineral; and $\mathbf{H}_{\text{ex}}$ is the intensity of the external magnetic field.

The observed magnetic susceptibility along a given direction of a grain is related to the intrinsic magnetic susceptibility of the mineral by

$$k_o = k_i / (1 + N_{ki})$$

For grains with weak intrinsic magnetic susceptibility ($k_i \ll 1$) – that is, for diamagnetic, paramagnetic, and anti-ferromagnetic particles – the Nk_i factor is negligible, so that the observed and the intrinsic magnetic susceptibility are practically equal ($k_o = k_i$). The magnetic anisotropy of these grains is controlled by crystallography. For grains with very high intrinsic magnetic susceptibility ($k_i \gg 1$) – such as for ferrimagnetic magnetite particles – k_o approaches the “self-demagnetization” limit value of $1/N$, and the magnetic anisotropy is controlled by particle shape.

The degree of magnetic susceptibility shape anisotropy in a grain is defined as

$$P = (1 + k_i N_c) / (1 + k_i N_a).$$

Therefore, the net effect of the shape anisotropy is to favor the orientation of the induced magnetization along the long

axis of a magnetic grain, where the internal demagnetizing field is minimized.

Magnetostriction: Stress Anisotropy

The application of an external stress to a rock may cause reversible as well as irreversible changes to its magnetic anisotropy. In fact, straining a ferromagnetic crystal can rotate its spontaneous magnetization away from the easy axis given by magnetocrystalline anisotropy. Moreover, the application of a magnetic field which rotates the spontaneous magnetization of a ferromagnetic crystal away from its intrinsic preferred direction can strain the lattice and modify the crystal shape, producing changes in its demagnetization factors and shape anisotropy. Both processes are expression of the phenomenon known as magnetostriction and are due to changes in the exchange energy when modifications in the magnetization or in the crystal shape alter the spin-orbit coupling in neighboring atoms.

Magnetostriction is defined as the spontaneous change in crystal dimensions that accompanies the process of magnetization or as the change in the magnetization of a crystal as a result of the application of stress. The linear saturation magnetostriction constant λ is defined as the fractional change in the length $\Delta L/L$ of a demagnetized ferromagnetic crystal as its magnetization increases from zero to saturation. Magnetostriction is positive when the crystal expands in the direction of magnetization. In magnetite, at room temperature, the magnetostriction depends crucially on the direction, being positive for a magnetization along a $\langle 111 \rangle$ easy axis but negative for magnetization along a $\langle 100 \rangle$ hard axis.

In a cubic crystal, the anisotropy of λ is given by (e.g., Dunlop and Özdemir 1997)

$$\lambda = 3/2 \lambda_{100} (\alpha_1^2 \gamma_1^2 + \alpha_2^2 \gamma_2^2 + \alpha_3^2 \gamma_3^2 - 2/3) + 3 \lambda_{111} (\alpha_1 \alpha_2 \gamma_1 \gamma_2 + \alpha_2 \alpha_3 \gamma_2 \gamma_3 + \alpha_3 \alpha_1 \gamma_3 \gamma_1),$$

where α_i ($i = 1, 2, 3$) are the direction cosines of saturation magnetization ($\mathbf{Ms}$) with respect to the $\langle 100 \rangle$, $\langle 010 \rangle$, and $\langle 001 \rangle$ crystallographic axes, respectively, and γ_i are the equivalent direction cosines of the direction along which the magnetostriction is being measured. λ_{100} and λ_{111} are the crystal's magnetostriction constants along the $\langle 100 \rangle$ and $\langle 111 \rangle$ crystallographic axes for $\mathbf{M}$ aligned in the same direction.

In the case of isotropic magnetostriction (i.e., $\lambda_s = \lambda_{100} = \lambda_{111}$), the magnetoelastic energy caused by the application of a stress σ to a magnetic crystal is given by

$$E = 3/2 \lambda_s \sigma \sin^2 \theta$$

where θ is the angle between $\mathbf{Ms}$ and σ .

In this simple case, the energy is minimum when $\mathbf{Ms}$ is parallel to σ and $\lambda_s \sigma > 0$ or when $\mathbf{Ms}$ is perpendicular to σ and $\lambda_s \sigma < 0$. Thus, the application of a uniaxial stress will cause $\mathbf{Ms}$ to rotate toward the stress axis if $\lambda_s \sigma > 0$ (i.e., under the combination of a compression and a negative λ_s or of a tension and positive λ_s).

In general, the relationship between the change in the magnetic anisotropy and the increase of strain induced by a stress field is not simple, reflecting the complex behavior due to the superposition of the strain effects upon an already magnetically anisotropic specimen.

Exchange Anisotropy

Exchange anisotropy results from superexchange interaction across the interface of two different magnetically ordered phases. In the simplest model, the origin of exchange anisotropy is considered to be the coupling of a ferromagnetic spin system to an antiferromagnetic spin system, separated by a planar interface. To obtain a preferred direction of the coupling, it is necessary that Curie temperature T_C of the ferromagnet is greater than the Néel temperature T_N of the antiferromagnet. When a magnetic field is applied at a temperature $T_N < T < T_C$, the spins of the ferromagnet will orient parallel to the applied field. Then, as the material is cooled through T_N , the spins of the antiferromagnetic lattice closest to the ferromagnet will align in the same direction as the ferromagnet, and subsequent spin planes in the antiferromagnetic lattice will orient antiparallel to each other. When the antiferromagnet is fully ordered, with high magnetocrystalline anisotropy, it holds the magnetization of the ferromagnetic material in the direction of the applied field, giving rise to a unidirectional magnetic anisotropy.

Exchange anisotropy can be detected from a shifted hysteresis loop when the material is cooled in a magnetic field and from the presence of a $\sin \theta$ term in torque curves measured in high fields due to a rotational hysteresis loss.

Exchange anisotropy in natural minerals has been found in titanomagnetite or in the intergrowth of maghemite with hematite and has been invoked to explain self-reversals in the direction of magnetization of natural rocks. In the last decades, there has been an increase of interest about this magnetic phenomenon because of the importance of its technological applications in spin-valve devices, such as hard disk read heads, and in magnetic thin layers.

Anisotropy of Magnetic Susceptibility (AMS)

Magnetic anisotropy of rocks is often determined by means of the analysis of the anisotropy of the magnetic susceptibility (AMS), which is the property that has found the most applications in geophysical studies so far. The anisotropy of magnetic susceptibility of rocks depends on mineral content,

their relative abundance, intrinsic susceptibility and anisotropy, preferential crystallographic orientation, and grain shape alignment. Therefore, knowing the composition of the rock-forming minerals and their magnetic anisotropy characteristics, it is possible to determine the spatial distribution of the grains and infer the geological processes that originated it. A preferential orientation-distribution of mineral grains is in fact typical of almost all rock types, and it develops during various geological processes, such as water flow in sediments, magma flow in igneous rocks, ductile deformation in metamorphic rocks, and even incipient strain in the paramagnetic clay matrix of apparently undeformed fine-grained sediments.

The magnetic susceptibility is the capability of a material to be magnetized under the effect of an external magnetic field. Being all the materials “susceptible” to become magnetized in the presence of an applied magnetic field, the magnetic susceptibility describes this transient magnetism within a material sample. If the magnetic field is relatively weak, the magnetization of a rock is a linear function of the intensity of this field. The low-field magnetic susceptibility is defined as the ratio of the induced magnetization ($\mathbf{M}$ dipole moment per unit volume or $\mathbf{J}$ dipole moment per unit mass) to the applied low-intensity magnetic field ($\mathbf{H}$). Only for isotropic substances, the induced magnetization is strictly parallel to the applied field, and the magnetic susceptibility is a scalar. In anisotropic media, like minerals and rocks, the induced magnetization is not parallel to the applied field, and the magnetization induced along the direction i is related to the magnetic field acting along the direction j by

$$\mathbf{J}_i = \chi_{ij} \mathbf{H}_j (\text{mass specific}) \quad \chi \text{ is given in SI units of m}^3/\text{kg}$$

or

$$\mathbf{M}_i = k_{ij} \mathbf{H}_j (\text{volume specific}) \quad k \text{ is dimensionless in SI units}$$

On the basis of the magnetic susceptibility, all substances may be classified as diamagnetic, paramagnetic, and ferromagnetic.

In diamagnetic minerals, the induced magnetization increases linearly with the increasing field, but in the opposite direction, the magnetic susceptibility is therefore negative and typically very low ($k \sim 10^{-5}$ SI). In paramagnetic minerals, the magnetization increases linearly with increasing field, along the same direction, and the susceptibility is positive ($k \sim 10^{-4} - 10^{-5}$ SI). In ferromagnetic minerals, the induced magnetization increases nonlinearly with increasing field, and the magnetic susceptibility is typically positive and much higher (k ranges from 10^{-3} to 10 SI) than in diamagnetic and paramagnetic minerals.

If the applied field is so low to approximate as linear the magnetic response of the body, the magnetic susceptibility

can be represented by a set of coefficients (k_{ij}) that form a second-order symmetric tensor. Each coefficient quantifies how much a body can be magnetized along a certain Cartesian direction according to a Cartesian component of the applied field. The relationship between the components of the magnetization $\mathbf{M}_i$ ($i = 1, 2, 3$) and the components of the magnetic field $\mathbf{H}_j$ ($j = 1, 2, 3$) is expressed by the equations

$$M_1 = k_{11}H_1 + k_{12}H_2 + k_{13}H_3$$

$$M_2 = k_{21}H_1 + k_{22}H_2 + k_{23}H_3$$

$$M_3 = k_{31}H_1 + k_{32}H_2 + k_{33}H_3$$

which can be rewritten in subscript notation as

$$\mathbf{M}_i = k_{ij} \mathbf{H}_j$$

where the coefficient k_{ij} defines a matrix that has six independent elements, since the second-order tensor must be symmetric to guarantee real eigenvalues, and k_{ij} is imposed equal to k_{ji} . Among all possible Cartesian reference systems, there exists one in which the non-diagonal terms of the tensor are zero so that the above equations simplify to

$$M_1 = k_{11}H_1$$

$$M_2 = k_{22}H_2$$

$$M_3 = k_{33}H_3$$

where in this case the three coefficients k_{11} , k_{22} , and k_{33} are the eigenvalues of the magnetic susceptibility tensor: they are called the principal susceptibilities and are generally indicated as $k_{\max} \geq k_{\text{int}} \geq k_{\min}$ (or $k_1 \geq k_2 \geq k_3$), the maximum, intermediate, and minimum susceptibilities.

The corresponding eigenvectors are the maximum, intermediate, minimum principal susceptibility directions that are the directions along which the induced magnetization is strictly parallel to the direction of the applied field. The magnetic susceptibility tensor may be represented geometrically by a triaxial ellipsoid, which is termed the magnitude ellipsoid, whose axes are parallel to the AMS tensor eigenvectors and whose semi-axes lengths are proportional to the AMS tensor eigenvalues, (Fig. 2). We will refer to this ellipsoid in the following as the AMS ellipsoid. Since for diamagnetic minerals it is possible to have negative AMS eigenvalues making the magnitude ellipsoid difficult to visualize, the magnetic susceptibility ellipsoid may also be expressed by the representation quadric, in which the length of the radius vector in any direction from the origin is equal to the inverse square root of the susceptibility in that direction. It has however a less direct relationship to the eigenvalues.

In practical measurements, the AMS eigenvectors are determined with two uncertainty angles, which define the regions where each principal susceptibility direction lies

Magnetic Anisotropy,

Fig. 2 The magnetic susceptibility ellipsoid. The AMS tensor may be geometrically represented by a triaxial ellipsoid, in which the three orthogonal axes correspond to the AMS eigenvectors, $k_{\max}$, k_{int} , and $k_{\min}$, respectively. The orientation of the AMS eigenvectors is then defined in a reference system of Cartesian coordinates (X, Y, and Z)

with a probability of 95% (Fig. 3). The definition of a magnetic susceptibility ellipsoid identifies two important elements: a “magnetic foliation” (the plane orthogonal to the direction of minimum magnetic susceptibility) and a “magnetic lineation” (the direction of maximum magnetic susceptibility).

AMS ellipsoid shapes are classified according to the relationships between the magnetic susceptibility eigenvalues:

$k_1 \approx k_2 \approx k_3$; isotropic susceptibility, the AMS ellipsoid is a sphere (Fig. 4a).

$k_3 \ll k_2 \approx k_1$; the AMS ellipsoid has an oblate shape (i.e., the magnetic fabric is planar, Fig. 4b).

$k_1 \gg k_2 \approx k_3$; the AMS ellipsoid has a prolate shape (i.e., the magnetic fabric is linear, Fig. 4c).

$k_1 > k_2 > k_3$; the AMS ellipsoid is triaxial (Fig. 4d).

The orientations of principal susceptibilities for a set of samples are conventionally visualized in a Schmidt equal-area projection, lower hemisphere (Fig. 5).

The bulk low-field magnetic susceptibility of a rock is a summation of the contribution from all mineral species composing the rock, weighted according to their relative abundance and susceptibilities. Obviously, the contribution of ferromagnetic minerals to the overall magnetic susceptibility of a rock specimen is overwhelming upon those of the paramagnetic and diamagnetic matrix. The contribution of the matrix will be negligible when the percentage of ferromagnetic minerals exceeds 0.1% ($k > 3000\text{--}4000 \mu\text{SI}$). Conversely, for rocks in which $k < 200\text{--}300 \mu\text{SI}$, the magnetic

Magnetic Anisotropy, Fig. 3 Relationship of the 95% confidence ellipses (e_{12} , e_{23} , e_{13}) to the AMS eigenvectors. Around each principal susceptibility axis, the major and minor semi-axes of 95% confidence ellipse lay within the planes defined by the eigenvectors

susceptibility is almost completely controlled by the contribution of the paramagnetic matrix. For very small or even negative k values (i.e., $k < 50 \mu\text{SI}$), the contribution of the

Squares, $k_{\max}$; triangles, k_{int} ; circles, $k_{\min}$. Small symbols indicate individual specimens, and large symbols indicate the mean tensor

diamagnetic matrix to the bulk susceptibility of a rock specimen is not negligible.

All the rock's constituent mineral fractions contribute to the development of an AMS fabric depending on their intrinsic susceptibility, crystalline and shape anisotropy at the grain scale, and degree of preferential orientation-distribution.

Among ferromagnetic minerals, hematite and pyrrhotite are the most anisotropic, both with anisotropy degree $P > 100$. Magnetite shows a typical range of P variation between 1.1 for nearly isometric grains and 3 for highly anisometric grains (Table 1). Paramagnetic minerals are characterized by a much smaller AMS degree. In biotite and most phyllosilicates, the $k_{\max}$ and $k_{\min}$ directions are, respectively, parallel and orthogonal to the basal plane, and their AMS ellipsoid is typically oblate. Finally, the main diamagnetic minerals typically show low magnetic susceptibilities and

low anisotropy (Table 1). A recent review of single crystal magnetic anisotropy for silicate and carbonate rock-forming minerals, as well as for accessory magnetic minerals (i.e., iron oxides and sulfides), is provided by Biedermann (2018).

AMS is determined from a number of susceptibility measurements taken accordingly to specifically designed sets of directions in magnetic susceptibility bridges. Commonly used susceptibility bridges operate with alternating current (AC). AMS can be measured manually or utilizing an automated sample handler. The choice of measurement axes for the determination of AMS is critical. A minimum of six measurements is necessary to solve for the six unknown components of the AMS tensor. A 15-measurement position scheme is typically utilized for AMS measurements in manual mode. New 3D automatic specimen rotators instead require the user to insert the specimen in one position only, and the specimen is then automatically rotated around two axes, taking a total of 320 measurements.

With the aim to enhance the paramagnetic contribution to the magnetic susceptibility and fabric, AMS measurements may be carried out also on samples kept at low temperatures (e.g., at liquid nitrogen temperature, ~ 77 K). This enhancement occurs because diamagnetic and, to the first order, ferromagnetic susceptibilities are temperature independent, whereas paramagnetic susceptibility increases by decreasing absolute temperature T according to the Curie–Weiss law, $k_{\text{para}} = C/(T - \Theta)$, where C is a constant value and Θ is the paramagnetic Curie temperature.

Recent instrumental implementation in susceptibility bridges allows the measurement of magnetic susceptibility and AMS in variable fields and frequency, as well as the simultaneous measurement of both the in-phase and out-of-phase susceptibilities and their anisotropies (Hrouda et al. 2017). Consequently, analytical techniques have been developed for direct determination of the magnetic subfabrics of magnetic minerals that exhibit low-field variation of susceptibility, frequency-dependent susceptibility, or measurable out-of-phase susceptibility, such as pyrrhotite, titanomagnetite, and magnetically viscous ultrafine superparamagnetic grains of magnetite or maghemite (Hrouda et al. 2017).

Magnetic Anisotropy, Table 1 Grain AMS determinations reported for various common minerals

Mineral	k (SI)	P	T	AMS type
<i>Ferromagnetic (s.l.)</i>				
Magnetite	2.0–5.7	1.1–3.0	Variable	Shape
Hematite	$1 \times 10^{-3} \div 5 \times 10^{-2}$	> 100	~ 1	Magnetocrystalline
Pyrrhotite	$5 \times 10^{-2} \div 3 \times 10^{-1}$	100–10000	~ 1	Magnetocrystalline

Adapted from Hrouda (1993, 2007); Tarling and Hrouda (1993), and Borradaile and Jackson (2004)

In comparison to other methods of petrofabric analysis, the study of AMS has the advantage to be quick, cost-effective, and highly sensitive, and above all, it can be performed systematically on all rock types. AMS data are usually employed to obtain information about the geological processes responsible of the fabric in rocks, both during lithogenesis and during any subsequent deformational event.

AMS: Applications in Geology and Geophysics

Magnetic anisotropy is an essential petrostructural phenomenon which can be used to study rock fabric, deformation, and various other processes that took place during the geologic history of a rock. The AMS of rocks can be determined with high accuracy, and the method is so sensitive that in rocks with a very weak preferred orientation-distribution of minerals, it is the only approach that gives reasonable results. The study of AMS has been therefore used as a tool of structural analysis for almost all rock types, and AMS analyses were applied to investigate a wide variety of geological processes capable to produce a preferential orientation-distribution of minerals in rocks. Moreover, AMS studies are an important complement to paleomagnetic researches, as a way to assess the reliability of paleomagnetic data and to determine possible deflections in the natural remanent magnetization components induced by deformation and compaction. For these reasons, the analysis of the AMS has experienced broad use in many branches of the Earth Sciences.

A brief overview of the wide spectrum of potential applications of the AMS research is provided below.

In undeformed **sediments**, the magnetic anisotropy may indicate the orientation of the sedimentation paleo-horizontal and eventual paleo-flow directions. The primary magnetic

fabric of sediments is strongly affected by the processes which govern deposition and compaction. In quiet water deposition, such as in a lagoon or lake environment, gravity-driven sedimentation brings platy grains to lay with their longer dimensions statistically parallel to the bedding-compaction plane. Then, with further sediment burial, the effect of diagenetic compaction on platy minerals by pressure and water expulsion reinforces the parallelism between the magnetic foliation and the bedding plane.

Thus, if the magnetic fabric is purely depositional, or related only to compaction loading, the AMS ellipsoid shows an oblate shape, with the $k_{\min}$ axis perpendicular to the bedding plane (which can be determined through AMS analyses with high accuracy) and the k_{int} and $k_{\max}$ axes mostly scattered in the bedding plane itself resulting in a wide uncertainty ellipse (Fig. 6a). The action of flow currents may cause the maximum susceptibility axis to be aligned either parallel or perpendicular to the paleocurrent direction (e.g., Hamilton and Rees 1970). In moderate currents, platy particles tend to imbricate, and elongated particles tend to align with their greatest axis parallel to the flow. On the AMS results obtained from a group of specimens, the imbrication induces a slightly vertical offset of the mean $k_{\min}$ and the clustering of the $k_{\max}$ axes in a direction antiparallel to the paleo-flow (Fig. 6b); the overall AMS fabric is still characterized by an oblate ellipsoid. In such a case, imbrication yields a better estimate of the flow direction than magnetic lineation, which may wander within the foliation plane and even be orthogonal to the flow direction. In fact, when deposition occurs under high current flow (traction transport mode of sedimentation), the distribution of $k_{\min}$ axes from various samples is streaked, the $k_{\max}$ axes cluster in a direction perpendicular to the flow (Fig. 6c),

Magnetic Anisotropy, Fig. 6 Schematic representations of the AMS development for undeformed sediments deposited in quiet conditions (a) under the action of weak or moderate water currents (b) and under the

action of strong currents, sufficient to entrain particles and to induce the rolling of elongated grains with their long axis perpendicular to the water flow (c). (Modified from Tauxe 2005)

and the fabric is characterized by prolate or triaxial AMS ellipsoids. The study of AMS was also applied in aeolian deposits of Chinese loess to reconstruct paleo-wind directions

and in recent and contemporaneous marine sediments to reconstruct the dynamics of deposition following tsunami events.

In general, sedimentary depositional fabrics are comparatively low both in susceptibility ($<10^{-4}$ SI) and in anisotropy ($P < 1.05$).

AMS measurements have been also combined with measurements of the anisotropy of P-waves velocity with the aim to analyze the 3D geometry of the pore space and to infer the anisotropy of permeability in porous rocks.

In **igneous rocks**, AMS analyses are mostly used to determine the orientation of the plane and flux direction of the magma flows. In these rocks, the viscosity of the magma plays a fundamental role for the genesis of a rock fabric. The movement/rotation of magnetic minerals is hindered when viscosity reaches a level which impedes any further ductile flow.

It is useful to distinguish the case of extrusive and shallow intrusive rocks (lava flows, ignimbrites, and dykes) from plutonic rocks. In volcanic rocks, the processes which induce a preferential orientation of the magnetic minerals (mostly titanomagnetites) are connected to the plane and direction of magma flow, both for lavas from effusive eruptions, for pyroclastic flows from explosive volcanism, and for dykes and other shallow tabular intrusive rocks (e.g., Cañón-Tapia 2004). Titanomagnetite grains are oriented in the flow plane with their greatest dimension parallel to the magma flow, so that for lava flows the magnetic foliation matches the (paleo) topographic surface, whereas for dykes or sills it develops parallel to the walls of the hosting rocks. The magnetic lineation is mostly parallel to the magma flow directions, even though perpendicular or oblique relationships can also be rarely found, especially in dykes. The efficiency of the volcanic flow to impart a preferential orientation on magnetic grains is usually relatively low, causing rather low anisotropy degrees, comparable to those typical of undeformed sediments.

A random fabric may be an indication of turbulent motion, which for dykes and sills occurs in the case of injection along wide enough fractures and for ignimbrites and surges occurs at a short distance from the vent where the eruption energy causes a chaotic motion of the transported solid particles. A coherent fabric may develop however at farther distance from the eruption centers where the kinetic energy decreases and the particles deposit on the morphological paleo-surfaces.

As for undeformed sediments, an eventual imbrication of the magnetic grains may be used to reconstruct the sense of the flow. In fact, the normal fabric of pyroclastic flows is considered the one with the foliation plunging upflow, so that the flow direction is given by the azimuth of the foliation pole and the lineation is close to it. AMS analyses in volcanic rocks have been used to constrain the location of the eruption centers.

In plutonic rocks, the analysis of the AMS may provide information on the processes of magma injection, emplacement, differentiation, and crystallization. The AMS fabric may therefore be affected by the flow of the magma, the

changes in its viscosity and composition, and the finite deformation it undergoes under regional stress before complete crystallization. Generally, the AMS of plutonic rocks whose magnetic fabric was produced through magma flow are characterized by a low anisotropy degree which overlaps with that of volcanic rocks and undeformed sediments. The shape of their AMS ellipsoid ranges from oblate to prolate according to the local character of the magma flow; the magnetic foliation is parallel to the flow plane, and the magnetic lineation is parallel to the flow direction. AMS fabrics of plutonic rocks have the potential to determine syn-magmatic deformation and to distinguish between compressional and extensional tectonic settings acting during emplacement. Conversely, the AMS of plutonic rocks which cooled under high temperature and pressures in the lower levels of the crust and are associated with metamorphic rocks may have a high anisotropy degree mostly determined by ductile deformation, which is a relatively efficient mechanism for the reorientation of magnetic minerals. The magnetic fabric in these rocks usually indicates a preferred orientation of magnetite minerals that nucleated at a late stage of the geological history of the pluton, and are therefore younger than the surrounding silicates. These magnetite grains grew in highly anisometric intergranular spaces and show therefore a high degree of shape anisotropy. This magnetic fabric is usually termed as mimetic magnetic fabric.

In **deformed rocks** AMS analyses are used to evaluate the orientation of the strain ellipsoid (e.g., Borradaile and Jackson 2010). In fact, AMS analysis is a very sensitive tool for the detection of rock strain, even in sediments that seem to have undergone weak or no deformation and where other strain markers are scarcely developed or even totally absent.

AMS studies in nearly undeformed sediments have also been used as a tool for recognizing intervals affected by significant coring-induced deformation and assess the reliability of paleomagnetic data derived from such sediments.

AMS is extremely sensitive to incipient strain, and it develops well before other macro- and mesoscopic strain features, such as cleavage, can be observed. As a matter of fact, the preferred orientation of phyllosilicate grains in mudstones may reflect the strain produced by compaction and tectonic processes. If there is a stress field acting on a sediment, causing progressive strain, the primary magnetic fabric is modified according to the nature and the extent of the deformation (e.g., Graham 1966; Parés 2015; Bilardello 2016) (Fig. 7). The first effect of strain upon such undeformed-compaction AMS fabric is to induce the clustering of the $k_{\max}$ axes in the direction of maximum stretching, that is, roughly perpendicular to the maximum compressive stress. The rotation of platy grains around the intermediate strain axis makes the planar bedding fabric less pronounced. Anyway, at such very first stage of deformation, the $k_{\min}$ axes are still normal to the bedding. AMS studies carried in clayey and weakly deformed sediments pointed out a

significant relationship between the magnetic fabric of apparently undeformed clays and the tectonic history of the sedimentary basins in which they were deposited, including compressional as well as extensional tectonic settings (e.g., Mattei et al. 1997). In such sediments, the magnetic foliation generally indicates the sedimentation-compaction plane, whereas the magnetic lineation is perpendicular to the shortening direction in the compressional settings and parallel to the stretching direction in the extensional settings. The magnetic lineation found in macroscopically undeformed fine-grained sediments from extensional settings develops from the spatial distribution of the basal planes of the paramagnetic phyllosilicates of the clay matrix and is parallel to the common axis of differently oriented basal planes (e.g., Cifelli et al. 2005). A further increase of strain under compression causes the dispersion (scattering) of the $k_{\min}$ axes in such a way that they tend to describe a girdle normal to the $k_{\max}$ cluster: the AMS ellipsoid becomes prolate, and the primary depositional fabric is progressively obliterated and overprinted by a tectonic fabric (Fig. 7). Mineral rotations are sufficient at this stage to produce a fabric strong enough to impart the well-known “pencil structure.” Further increasing strain occurs entering in the field of metamorphism and leads to the

progressive return of the AMS ellipsoid into the flattening field. Mineral rotation leads to the production of an imperfectly formed cleavage crossing bedding, called embryonic cleavage. A cleavage stage is achieved when the tectonic strain imprint is sufficiently strong to form a dominant planar cleavage fabric, where platy and acicular minerals are oriented in this cleavage plane. The magnetic foliation plane which develops at this stage is parallel to the plane of cleavage or schistosity visible in the rock. With increasing strain, the planar cleavage and lineation are intensified, this last one very close to or parallel to the strain maximum stretching direction (Fig. 7). Recent studies extended the range of magnetic fabric investigations in deformed rocks to address a wide variety of other geological problems, such as the mechanism of emplacement of large salt bodies, the cumulative strain due to glacier flow in tills and glacioteconites, the estimation of the shock pressure in weakly shocked rocks from an impact crater, the mechanism of recrystallization, and penetrative deformation along major faults planes and cataclastic fault rocks in shallow faults exposed at the earth surface.

The AMS of **metamorphic rocks** is generally considerably higher than the AMS in undeformed sedimentary and volcanic rocks. As a matter of fact, the mechanisms of ductile

Magnetic Anisotropy, Fig. 7 Schematic representations of the sequence of AMS development in progressively deformed sediments in a compressional setting. (Redrawn after Graham 1966)

deformation and recrystallization operating during metamorphism (e.g., diffusion, crystal plasticity, particulate flow, neomineralization) may be very effective to determine a preferential orientation-distribution of magnetic grains. AMS has been investigated also in the thermometamorphic aureole rocks surrounding igneous plutons with the aim to reconstruct the finite strain patterns acquired at the peak of contact metamorphism and to constrain mechanisms of pluton emplacement. In rocks with strong tectonic fabrics, the principal directions of susceptibility and of finite strain coincide, and a quantitative genetic relationship between strain and AMS has been pointed out in some cases (see review by Borradaile and Jackson 2010). Nevertheless such relationships are not universal, and strain-AMS relationship or correlations found under certain circumstances and lithologies cannot be extrapolated to different situations.

A magnetic fabric is defined normal when the principal magnetic axes correspond one by one to the petrofabric axes. An inverse or intermediate magnetic fabric occurs when the magnetic susceptibility principal axes exchange their position. Inverse AMS fabrics are associated with the prevalence of certain magnetic minerals (see Rochette et al. 1992). Specifically, some minerals possess an inverse AMS fabric related to their shape (e.g., goethite and tourmaline) or to intracrystalline gliding during ductile deformation (e.g., siderite and other iron-bearing carbonates). Moreover, SD ferrimagnetic particles with prolate shape anisotropy may originate an inverse magnetic fabric as well. As a matter of fact, pseudo single domain (PSD) and multidomain (MD) particles of a ferrimagnetic mineral such as magnetite have a maximum susceptibility parallel to their long (easy) morphological axis, while a stable single domain (SD) magnetite particle, whose magnetization is always saturated along its long axis, has a maximum susceptibility value perpendicular to it. Even if inverse and anomalous AMS fabric are relatively rare in nature, in all cases when AMS directions cannot be correlated with obvious structural markers, the mineralogical source of the AMS should be closely investigated and the AMS compared with other types of magnetic anisotropy (i.e., the anisotropy of artificially induced magnetic remanences).

Anisotropy of the Magnetic Remanence (AMR)

AMS represents the sum of the susceptibility anisotropies of all the mineral components in a rock, including the diamagnetic and paramagnetic fractions. Studies on the anisotropy of the magnetic remanence (AMR) are directly relevant to paleomagnetic studies, since they only measure the anisotropy of the remanence carrying particles. AMR studies also have a large spectrum of application in geological sciences (e.g., see Jackson 1991).

In fact, AMS may be inappropriate for the purposes of correcting paleomagnetic data, since it depends critically on the size of the remanence carrying particles. One of the advantages of AMR is that it precludes the effect of inverse AMS fabric due to single domain magnetite, since the grain long axis is the axis of maximum remanence irrespective of particle size. The most common ARMs are anisotropy of anhysteretic remanent magnetization (AARM) and anisotropy of isothermal remanent magnetization (AIRM) (see review by Bilardello 2016).

AARM: Anisotropy of Anhysteretic Remanent Magnetization

The anisotropy of anhysteretic remanent magnetization (AARM) is the most commonly studied anisotropy of remanence. An anhysteretic remanent magnetization (ARM) is acquired by a sample when it is simultaneously exposed to an alternating magnetic field with decreasing amplitude (usually with a maximum peak in the range 10–100 mT) and a steady DC magnetic field (typically values close to the intensity of the geomagnetic field, e.g., about 50–100 μ T). Prior to acquisition of the ARM, the specimen should be demagnetized in an AF peak higher than that used for the ARM acquisition and its residual remanence measured as a baseline. Then the ARM is imparted and computed as the difference between the measured remanence and the baseline.

There are two principal advantages of using ARM for the characterization of the anisotropy of the remanence: (1) the acquisition curve of ARM versus DC field is expected to be linear in the range of low DC magnetic field commonly employed, and (2) a window of AC field can be used to impart ARM. In fact, by measuring different windows of coercivity (partial AARM), one can expect to characterize different subpopulations (size and shape) of ferromagnetic grains.

The ferromagnetic particles that define the AARM tensor may have a broad range of grain sizes.

Since there is a strong empirical correlation between partial anhysteretic remanent magnetization (pARM) and magnetite grain size (e.g., Dunlop and Özdemir 1997), it is possible to isolate the AARM tensor associated with distinct populations of grains by using partial rather than total anhysteretic remanence anisotropy. This can be done by imparting a magnetization to a specific particle fraction during anisotropy determinations.

Observed AARM indicates possible anisotropy in acquiring NRM. This provides a warning that the rock might not be an accurate paleomagnetic recorder. Measuring the AARM thus provides a fast and reliable method to correct paleomagnetic deviation in rocks. In sedimentary rocks, AARM has been proposed to provide a quantitative correction for inclination error and to correctly evaluate the amplitude of paleosecular variation recorded in volcanic rocks.

AIRM: Anisotropy of Isothermal Remanent Magnetization

Another type of magnetic anisotropy is the anisotropy of isothermal remanent magnetization (AIRM). In order to study the IRM anisotropy, a sample is successively subjected to a pulse magnetic field (with intensity generally of the order of 5 mT to 60 mT) in several appropriate directions, and the acquired IRM is measured. As for the study of the anisotropy of ARM, before the measuring process and after each magnetization step, the sample is AF demagnetized. Stronger magnetic fields (e.g., higher than 1.3 T) were used to produce IRMs in red beds where multiple magnetic minerals coexist, like hematite and magnetite: the IRMs magnetize all the phases present, and the subsequent AF treatment will only demagnetize the low-coercivity magnetite, allowing determination of the remanence anisotropy of high-coercivity hematite only. The determination of the IRM anisotropy makes it possible to study the ferromagnetic fraction of a rock separately from the contribution of the paramagnetic and diamagnetic matrix.

Although usually successful, AIRM risks nonlinear effects where strong magnetic field is required.

HFAMS: High-Field Anisotropy of Magnetic Susceptibility

High-field methods are used to separate the AMS due to ferromagnetic minerals from the AMS due to diamagnetic and paramagnetic minerals. These methods are based on the field dependence of the magnetic susceptibility and rely on the different responses of ferromagnetic and paramagnetic minerals to large applied fields, i.e., large enough to saturate the ferromagnetic mineral fraction. For rocks that have both ferromagnetic and paramagnetic minerals, changes in magnetization at fields greater than ferromagnetic saturation are due primarily to the paramagnetic susceptibility.

High-field magnetic anisotropy measurements have been made using torque magnetometers or a high-field, rotating sample, cryogenic magnetometer. Although these techniques have great potential to separate paramagnetic and ferromagnetic fabrics, torque magnetometers and high-field cryogenic magnetometers are not available in most magnetic laboratories, and HFAMS is not routinely applied.

Summary

Magnetic anisotropy is an essential property of rocks and minerals.

The anisotropy of magnetic susceptibility (AMS) of rock specimens can be determined with a high degree of precision,

and the method is sensitive, rapid, and nondestructive. The study of AMS is a fundamental tool of petrofabric analysis, which has the potential to recognize even subtle preferred orientations of mineral lattices or shapes and to infer the causative processes, ranging from the effects of paleocurrents in undeformed sediments to pervasive strain in deformed rocks. As such, it has a wide range of applicability in the Earth Sciences.

The anisotropy of the magnetic remanence (AMR) instead refers to the preferential orientation-distribution of the ferromagnetic grains only. The techniques to determine AMR are time-consuming because artificial remanences must be applied and then removed along each measurement axis. The study of AMR is more directly relevant to paleomagnetic researches since it may provide a tool to correct paleomagnetic deviations in all cases when the direction of the magnetic remanence is deflected from the direction of the magnetic field in which it was acquired.

Definition

Magnetic anomaly. On Earth, magnetic anomalies are defined as the vector and/or scalar differences between the measured magnetic field and estimations of the primary Earth's core and external magnetic fields. Magnetic anomalies are commonly assumed to reflect the magnetic structures of the rocks lying in the Earth's crust and the upper part of the lithosphere.

Introduction

The Earth's magnetic field is the sum of fields of internal and external origins that operate on a wide range of spatial and temporal scales (Hulot et al. 2007). The three major magnetic field sources are the core field, which is generated by electrical currents in the liquid outer core, the external fields produced by currents in the ionosphere and the magnetosphere, and the crustal field, which results from magnetized materials in the outer layer of the Earth. An anomaly field after correction for core and external fields is assumed to reflect the magnetic field of the Earth's crust. This field is one of the weakest one detectable at the altitudes of low Earth orbit (LEO) satellites. Inferring it with accuracy depends on the operator's ability to model and then to correct for core and external fields considered as perturbation fields. When the total magnetic field is measured globally in the geocentric reference frame, along the orbits of satellites for example, it may be expressed in current-free regions as the vector $\mathbf{B} = -\nabla V(\mathbf{r}, \theta, \phi, t)$ of the scalar magnetic potential V that is expanded in terms of spherical harmonics (SH):

$$\begin{aligned} V(r, \theta, \phi, t) &= a \sum_{n=1}^{\infty} \sum_{m=0}^n \left(\frac{a}{r}\right)^{n+1} (g_n^m(t) \cos(m\varphi) + h_n^m(t) \sin(m\varphi)) P_n^m(\cos \theta) \\ &+ a \sum_{n=1}^{\infty} \sum_{m=0}^n \left(\frac{r}{a}\right)^n (q_n^m(t) \cos(m\varphi) + s_n^m(t) \sin(m\varphi)) P_n^m(\cos \theta). \end{aligned} \quad (1)$$

The parameters a , r , θ , and ϕ are, respectively, the Earth's reference radius (6371.2 km), the radius, the colatitude, and the longitude. The internal (g_n^m, h_n^m) and external (q_n^m, s_n^m) coefficients may be time varying and are expressed in the unit of nT with respect to the shell of radius a . In geomagnetism, the functions $P_n^m(\cos \theta)$ are the Schmidt semi-normalized-associated Legendre functions of integer degree n and order m . The spatial power spectrum in SH for the internal field writes (Lowes 1974)

$$R_n = (n+1) \left(\frac{a}{r}\right)^{2n+4} \sum_{m=0}^n [(g_n^m)^2 + (h_n^m)^2], \quad (2)$$

with R_n expressed in the unit of nT^2 . The power spectrum provides an estimate of the contribution of each SH degree n to the square amplitude of the observed magnetic field of internal origin at the radius r . The horizontal spatial wavelength λ in kilometers [km] at the Earth's mean radius a associated with each degree n is approximated by the relationship to the SH degree n (Backus et al. 1996, p. 101):

$$\lambda = \frac{2\pi a}{n}. \quad (3)$$

Magnetic Anomalies: Interpretation, Fig. 1 Geomagnetic field power spectrum to SH degree 800 at the mean Earth's radius. The core magnetic field (in red) is the IGRF predicted at epoch 2020.0 (Thébault

et al. 2015), and the lithospheric field (in blue) is computed from the WDMAM2.0. (After Lesur et al. 2016)

Figure 1 displays the power spectrum of an internal SH model expanded to SH degree $n = 800$ (Lesur et al. 2016). It includes contributions from the core and the crustal internal fields only. It is derived from the CHAMP and the Swarm trio of satellites, from airborne and ship measurements (► [Geomagnetic Field, Measurement Techniques](#)). The power spectrum shows a break around the SH degrees 13–15 that indicates the primary contribution of the long-term dynamo processes (the core field and its secular variation; see ► [Geomagnetic Field, Secular Variation](#)) at lower SH degrees. This contribution hides the crustal field structures from SH degrees 1 to 13–15. The magnetic field of the Earth's core is dynamic and more complex than a simple dipole (a simple dipole would concentrate all the energy on the SH degree $n = 1$). Many core field models based on different data, processing, and modeling techniques are available. The disagreements between the core field models for the same epoch lead to different pictures of the anomaly field. The most widely used core field model is the International Geomagnetic Reference Field (IGRF) model that was derived to SH degree 10 prior to epoch 2000.0 and to degree 13 thereafter (► [Geomagnetic Field, IGRF](#)).

The geometrical attenuation of SH harmonics with increasing altitudes is a major impediment to the detection of the lithospheric field at all scales, particularly the smallest ones. The fast coalescence of small-scale anomalies implies that magnetic measurements at different heights are not

sensitive to the same horizontal length scales. This calls for accurate core field models as well as techniques for removing the best estimates of external fields that could be quasiperiodic but are in general transient. At LEO satellite altitudes, a common practice is to select subsets of quiet-time data and to accumulate a large number of data over time in order to increase the signal-to-noise ratio and then to highlight the finest permanent crustal field structures. The spatial resolution of a magnetic anomaly thus depends on altitude and on the care taken to remove all field contributions not originating from the lithosphere. Its robustness is strongly related to the advances made toward analyzing and understanding the Earth's magnetic field as a whole. Correcting accurately for perturbation and transient external fields is the main cause of differences between lithospheric field models derived by independent groups and at different epochs, particularly those corresponding to periods of strong solar activity.

The Sources of Crustal and Lithospheric Fields

When the errors incurred in correcting the data for core and external fields are minimized, the anomaly field is assumed to have its sources buried in the crust (► [Continental Crustal Structure](#)) or deeper in the upper lithosphere although this remains a scientific debate (► [Lithosphere, Continental: Thermal Structure](#)).

The subject of rock magnetism is complex (Dunlop and Özdemir 2007), but the general mechanisms are well-known, thanks to laboratory experimental measurements made on rock samples. The amount of magnetization carried by a rock depends on several parameters such as its size, shape, mineralogy, grain domains, crustal thickness, and temperature (► [Magnetic Domains](#); ► [Remanent Magnetism](#)). Most magnetic minerals present on Earth are titanomagnetite and titanohematite, for which the Curie temperature is between 580 °C and 670 °C (► [Curie Temperature](#)). Considering the geothermal gradient of the Earth, the Curie temperature is met at about 30 km depth in stable continental regions and at 7 km depth in the oceans. These mean estimates vary significantly with the geographical location. Deeper rocks are thus considered nonmagnetic.

The minerals found in the Earth carry both permanent, $\mathbf{M}_r$ (► [Remanent Magnetism](#)), and induced magnetizations, $\mathbf{M}_i$. The magnetization, $\mathbf{M}_r$, arises when the magnetized grains of a hot material are locked in the direction of the Earth's global field when the temperature of an igneous rock decreases below the Curie temperature of its magnetic phase. The remanent magnetic field represents a small fraction of the ancient magnetic field, whose direction may be different from the contemporary field both because of rock reorientation to their present positions and because of changes of the main field directions over geological times (► [Geomagnetic Field, Polarity Reversals](#)). The ease with which a material can acquire induced magnetization depends on the magnetic susceptibility k such that $\mu_0 \mathbf{M}_i = k \mathbf{B}$, where $\mathbf{M}_i$ is the vector of induced magnetization, $\mathbf{B}$ the inducing ambient field, and μ_0 the magnetic permeability of free space. Susceptibility values vary with rock types, but the mean bulk susceptibility of the Earth's crust is about 0.02 SI. Therefore, the induced magnetization produces a field much less intense than the inducing field. Since the magnitude of the Earth's core magnetic field does not vary significantly on a decadal time scale (► [Geomagnetic Field, Secular Variation](#)), the induced lithospheric field may be considered as quasi-static over historical times so that accumulation of measurements over years is made possible. Nevertheless, some predictions indicate that the time variations of this field may become significant over decades (Thébault et al. 2009; Hulot et al. 2009) so that data accumulation over long periods of time or between distant epochs may introduce errors. The total magnetization $\mathbf{M} = \mathbf{M}_i + \mathbf{M}_r$ responsible for the observed crustal field points toward a different direction from both the present and the ancient fields. The Königsberger ratio M_r/M_i measures the relative importance of remanent to induced magnetization in the laboratory. Without collecting rock specimens and measuring their magnetic properties in the laboratory, it is difficult to resolve accurately the magnetization into its induced and remanent components. However, the Königsberger ratio is generally large for oceanic rocks. The rather homogeneous

nature and structure of the oceanic crust (► [Lithosphere, Oceanic](#)) also allows inferring the remanent magnetization over the extent of oceanic crusts by interpolating the magnetic properties between geographically distant samples (see ► [Paleomagnetism, Principles](#)). In contrast, it is almost impossible to predict the remanent magnetization over continents and to separate it from the induced one. A common practice is to disregard remanent magnetization on continental areas because rock materials contain coarse magnetite grains. However, these first-order approximations are questionable for detailed analyses as their validity depends on the length scales of the magnetized structures under consideration.

Measuring Magnetic Anomalies from Planes and Ships

Near-surface surveys are routinely undertaken for mineral and hydrocarbon exploration and sometimes for the delineation of structures buried at depth. Airborne magnetic surveys are generally carried out to support mineral and petroleum exploration and aid in subsurface geological mapping (► [Magnetic Methods, Airborne](#)). These surveys are commonly executed on a regular pattern at some hundred meters altitude above mean terrain clearance, with a horizontal distance about twice as much as the aircraft altitude (Reeves 2005). The flight lines are oriented perpendicular to the geological strike directions to detect better the magnetic field contrasts. For reconnaissance mapping of large regions (e.g., states or countries), typical line spacing is 1 km between 1 and 5 km altitude above the sea level or above the topography. More widely spaced segments crossing the flight lines at right angles are then used to correct the measurements for offsets caused, either by external magnetic field time variations or by measurement and attitude errors.

The local and regional surveys do not detect the same structures of magnetic anomalies. Low-altitude surveys provide locally detailed profiles of short-scale magnetic field contrasts but little information about the magnetic structures exceeding the survey dimension. Likewise, high-altitude surveys provide a synoptic view of the magnetic anomalies but generally are not sensitive to the features with length scales smaller than the altitude of measurements. Theoretically, it is possible to highlight all magnetic field structures from one single altitude measurements by continuing the map downward close to the source layer. However, this procedure enhances the noise, and unless the measurements are accurate enough, the finest structures are distorted or inaccessible.

The anomaly field is defined by correcting the raw data for a core field model, either with complex magnetic field models or more generally with the International Geomagnetic Reference Field model (► [Geomagnetic Field, IGRF](#)), or

simply with *ad hoc* regional trend corrections. External field variations that occurred during the survey are sometimes explicitly corrected for. In this latter case, current practice is to use the magnetic records of nearest magnetic observatories or a nearby ground station purposefully set up during the survey acquisition. This procedure allows monitoring the transient disturbances and correcting for them. In most cases, the external field is further minimized by statistical or manual analyses of crossovers between the flight lines and by applying line-leveling algorithms. The final product is a map of anomaly values built by interpolation between data points and leveled to a common altitude onto a regular grid. An anomaly map built upon the compilation of various surveys displays crustal features with typical spatial scales from kilometers to hundred kilometers. However, because of their limited lateral extension, the stitching of different panels, and sometimes differences in the data processing protocol applied, they are more sensitive to magnetic field structures lying in the upper part of the crust.

Satellite Measurements

Large geologic structures with dimensions of a few hundred kilometers can be inferred from LEO satellites. Satellites provide scalar and vector homogeneous measurements at the Earth's scale (► [Magnetic Methods, Principles](#)). At the LEO satellite altitudes, the lithospheric field is one of the weakest detectable sources. It represents less than 0.1% of the full signal, and magnetic anomalies rarely exceed 20 nT in amplitude (► [Magnetic Methods, Principles](#)). Satellites are also close to (and sometimes fly through) the electrically conductive ionosphere. At satellite altitudes, ionospheric fields external to the Earth's surface are seen as internal ones, and the separation between internal and external source fields is more challenging than for airborne measurements. Satellite measurements may be exploited globally to co-estimate the core and the lithospheric field in SH, an operation difficult to perform with airborne and marine measurements. This co-estimation considerably limits the error introduced by correcting the data with an independent core field model such as the IGRF ones. Data selections during nighttimes permit to mitigate the contamination of the ionospheric magnetic field variations more prominent in the day-side. Magnetic field proxies developed from ground surface magnetic field observatory measurements are also extensively used to select the measurements during magnetospheric quiet times only. The lithospheric field models derived from space are then more conveniently continued downward to the Earth's surface even if this procedure amplifies the noise.

The motion of a satellite represents another source of ambiguity. As it is constantly moving along its orbit, its displacements create signals that can be interpreted in terms

of genuine lithospheric field spatial variations or in terms of time-varying perturbation magnetic fields. Altitude uncertainties of the spacecraft, time errors, misalignment of magnetometers, and the absence of baseline control introduce a total error whose magnitude is enhanced by the large spacecraft velocity. At about 7.5 km.s^{-1} at 400 km altitude for the CHAMP and Swarm satellites (Reigber et al. 2002; Olsen et al. 2013), such uncertainties can convert into a few nT error. The absence of traverse lines and the low number of crossovers also introduce North-South artificial stripes that may easily be confused with genuine anomalies when the satellite measurements are analyzed orbit by orbit (Thébault et al. 2012). Therefore, contrary to aeromagnetic data that need to be acquired once, only long periods of observations and data accumulation over the same area allow improving the signal-to-noise ratio at satellite altitudes. After almost two decades of nearly continuous measurements, the lithospheric field signal still drops into the noise somewhere between SH degree 90 and 100. CHAMP satellite measurements down to 250 km altitude and the innovative use of magnetic gradients measurements from the ongoing Swarm mission (Friis-Christensen et al. 2006) improved the view of the Earth's lithospheric magnetic field up to SH degree 130 (about 350 km wavelengths). Further, a priori assumption and regularization are also applied to extend models to higher SH degrees (Olsen et al. 2017). However, at these wavelengths close to the satellite resolution, lithospheric field models derived from space differ and have a typical standard deviation of about 0.5 nT at the mean altitude of 400 km. Lower-altitude measurements would enhance the signal-to-noise ratio but would reduce the lifetime of satellites. Finding the best trade-off between signal detection at short length scales, lifetime, and data accumulation remains challenging.

When merged together, aeromagnetic and satellite data provide a complementary view of the lithospheric field. Yet, it is suspected that these combined models have a loss of gain between 200 and 400 km wavelength because of the lack of intermediate altitude data between airplanes and satellites. Current efforts focus on ways to improve the resolution achievable from space by considering gradient measurements and constellation of satellites such as the Swarm trio of satellites. As a follow-on to the Swarm mission, the community investigates the feasibility of sending at lower costs a constellation of cube satellites in order to perform simultaneous multipoint magnetic field measurements on different orbits.

World Magnetic Anomalies: WDMAM

Homogeneous global lithospheric magnetic field models are essential for evaluating the crustal structures, understanding the geological processes, for establishing tectonic models of

continental and oceanic crust, for reconstructing the geometry of paleocontinents, and for contributing to geodynamic models. The merging of ground, near-surface, and satellite measurements is the only way to access this multi-scale view of the Earth's lithospheric magnetic field. The World Digital Magnetic Anomaly Map (WDMAM) project is an international effort directed toward compiling magnetic anomaly data available in the public domain at the worldwide scale (Korhonen et al. 2007). The updated version of the WDMAM is based upon more than 50 years of aeromagnetic and marine surveys and uses recent satellite lithospheric field models. It is available as a 3 arcmin spacing grid at 5 km altitude (Lesur et al. 2016). It relies on published continental-scale compilations derived by independent groups (e.g., the North Atlantic Magnetic Anomaly Group (NAMAG) or the Antarctic Digital Anomaly Map (ADMAP)), upon independent contributions from countries and individuals, and most recent lithospheric field model derived from the Swarm mission (Fig. 2). Continuous efforts are being made to improve the quality and the data coverage from airplane, marine, and satellite platforms to release updated grid maps of the WDMAM (www.wdmam.org).

Qualitative Interpretations

Most susceptibility contrasts may give rise to a magnetic field detectable by a magnetometer (► [Geomagnetic Field, Measurement Techniques](#)). Magnetic surveys are traditionally acquired for resource exploration in order to detect ore bodies, but also oil and natural gases, which are trapped in sedimentary basins. Magnetic maps are also useful to track anthropogenic buried materials, like unexploded bombs,

hidden weapons, and abandoned oil wells, but may also be used for guiding archaeological excavations.

At a regional scale, mapping the patterns of magnetic anomalies is a very effective way of reconnoitering large areas of geology (Purucker and Whaler 2007) in remote regions where rock outcrop is absent and bedrock covered by glacial, sand, vegetation, or water overburdens. In particular, the interpretation of magnetic anomalies over oceans was crucial to the development of the plate tectonic paradigm (Vine and Matthew 1963). Over continents, tectonic processes are detailed in a magnetic anomaly map because they are responsible for the creation, destruction, and movement of magnetic materials within the lithosphere that modify pre-existing magnetic signatures. New magnetic contrasts are created by volcanism and related igneous processes such as dike emplacement, rifting, and faulting.

At a continental scale, magnetic anomalies are particularly prominent above the main old and cold continental masses over Africa, Antarctica, Asia, Australia, Europe, Greenland, India, and North and South America (Fig. 2) and comparatively weaker over younger and hotter oceans (at least from space; see ► [Magnetic Methods, Principles](#)). The largest magnetic anomaly features correlate well with cratons, Precambrian and Paleozoic provinces. Within each structure, magnetic anomalies of smaller extension like mobile belts, collision zones, and volcanic areas can be characterized. Crustal thickness variations at continent ocean boundaries and large subduction zones are also sometimes outlined with a strong correlation between the seismic Mohorovicic (Moho) discontinuity and the magnetic crustal thickness. Large magnetic anomalies often correlate with plate boundaries and seismotectonic activity around the world. Reconstructions of wide separated geological units or rotated blocks make

Magnetic Anomalies: Interpretation,

Fig. 2 Lithospheric magnetic field model derived from CHAMP, Swarm, and the WDMAM grid. (After Lesur et al. 2016. Projection is Mercator)

extensive use of the seafloor stripes and transform faults' magnetic signatures.

The picture of a magnetic anomaly is generally more understandable after a procedure of pole reduction that transforms an observed magnetic anomaly into the anomaly that would be measured at the north magnetic pole. The pole reduction method corrects for the induction effect by relocating the magnetic anomalies so that its maximum lies in the middle above the magnetized body. The flank of anomalies may also be clarified by upward and downward continuation, and depth estimations are obtained by the application of numerical filters under simplifying approximations (see Baranov (1975) for an overview of these techniques).

Quantitative Geological Interpretations

The quantitative interpretation of magnetic maps directly in terms of true magnetization is difficult. A single magnetic anomaly can be caused by an infinite variety of magnetized bodies. Moreover, not all magnetization distributions produce magnetic fields detectable above the Earth's surface (Runcorn 1975). The spatial variations in the measured magnetic field reflect lateral contrasts of magnetization rather than the magnetization itself. Two adjacent geological units possessing both strong and comparable magnetization may produce a magnetic field comparable to the field of two bodies with smaller magnetization. Outcropping geological obvious features that do not necessarily have a detectable magnetic signature as part of the magnetization is hidden in the crust (Gubbins et al. 2011; Vervelidou and Lesur 2018). The interpretations of magnetic maps in terms of magnetization distribution of rock in the crust therefore generally require additional geophysical information. For this reason, the inferred magnetization from field models is referred to as the apparent bulk magnetization.

Locally, on continents, a quantitative description of a magnetized body is performed by using processing techniques inherited from Fourier analyses. It can also be achieved by setting a distribution of equivalent magnetic dipoles in the subsurface and interpreting the observed anomaly in terms of inducing field (► [Magnetic Anomalies: Interpretation](#)). When the geometrical parameters of the geological source are bounded, the magnetization of a body can be found by trials and errors by a comparison with the magnetic measurements (► [Magnetic Anomalies: Interpretation](#)), and its rock type can be subsequently inferred from a table of rock magnetization (► [Magnetic Domains](#); ► [Remanent Magnetism](#)). In most areas, interpreting individually each magnetic anomaly is not straightforward if the geophysical body has a complex geometry. In such cases, it is more convenient to analyze the magnetic signal statistically in the spectral rather than in

the geographical domain. This allows estimating the average source depth on various length scales (Thébault and Vervelidou 2015) or estimating the statistical contribution of the induced and remanent fields by comparisons with theoretical power spectra. Maus and Haak (2002) verified, for example, that the lithospheric magnetization was statistically mostly induced over continent and remanent over oceans at the wavelengths detected by the LEO satellites. The spectral analysis justifies that in the geographical domain, the anomaly field over continent can be approximated by the anomaly field produced by an array of equivalent dipole with moments aligned along the main core field.

The ambiguities in interpreting the magnetic anomaly maps can be further reduced by requesting guidance from other disciplines like, gravity, seismology, heat flux, geology, etc. The geophysical approach that consists in analyzing crustal field models in large integrated geophysical system requires an extensive work for linking analytically or numerically the large number of geophysical parameters responsible for the magnetic field signal. So far, simplifying assumptions are still necessary. Such approximations are more easily justified from space as the magnetization can be assumed to vary laterally and to be contained in a crustal layer of constant thickness as at 400 km altitude, the Earth's crust appears as a thin layer.

The consideration of the bare thickness contrast between continental (~30 km) and oceanic (~7 km) crusts of uniform, but different, susceptibility values generates magnetic anomaly field that is seen in magnetic field measurements along the boundaries of oceans and continents (Counil et al. 1991). This indicates that magnetic crustal thickness plays a significant role in the dichotomy between oceanic and continental magnetic field signals observed from space (see ► [Magnetic Methods, Principles](#), Fig. 1). Cohen and Achache (1994) further introduced a model of oceanic topography to estimate a more realistic crustal thickness in some oceanic areas; they could explain the magnetic anomalies observed over oceanic plateaus. On ocean bottoms, remanent magnetism predicted by Dyment and Arkani-Hamed (1998) and compared to measurements could explain well large magnetic signatures over superchrons in the North Atlantic and Indian oceans. This modeling approach could in turn be also used to infer the magnetization distribution of the ocean floors with interpolation/extrapolation techniques (Masterton et al. 2012; Dyment et al. 2015). Following these studies, Hemant and Maus (2005) merged these different approaches in an attempt to predict all structures of the lithospheric field seen at satellite altitudes and to estimate the worldwide distribution of the rock susceptibility integrated within the entire crustal thickness (Fig. 3). They relied on a priori geophysical data about the nature of the magnetization, the susceptibility of continental rocks, the stratification of the crust, the depth to the Moho, and the boundaries of the geological units at a global

Magnetic Anomalies: Interpretation, Fig. 3 Map of the equivalent susceptibility of the Earth's magnetic crust in SI.km. (After Hemant and Maus (2005) updated with the Swarm lithospheric magnetic field models. Projection is Mollweide)

scale. Their forward model was subsequently compared to the lithospheric field model derived from the CHAMP measurements. They could show that our understanding of the Earth's magnetic lithosphere was to a first order statistically reasonable at large wavelengths but mostly failed at the smaller wavelengths. Moreover, the long-standing question concerning the presence of magnetization within the upper lithosphere could not be addressed. Some geophysical arguments suggest that magnetization could persist below the Moho seismic discontinuity (Ferré et al. 2014). However, estimation of the magnetic crustal thickness by trials and errors from iterative comparisons between the forward-predicted crustal fields with observed satellite magnetic anomalies (Purucker et al. 2002) and independent regional statistical analyses of models does not support this conclusion (Vervelidou and Thébault 2015). The presence of magnetization in the upper lithosphere remains a crucial question for inferring the thermal state and the composition of the crust/lithosphere (Fox Maule et al. 2005).

Summary

On Earth, a magnetic anomaly is defined with respect to the core and the external fields that are considered as perturbation magnetic fields. Characterizing the anomaly field and depicting all spatial dimensions are challenging as data processing leading to anomaly maps differs with the altitudes and the epochs of measurements. Nowadays, the main sources of discrepancies are the rapid temporal changes of the external magnetic field that remain poorly sampled. Magnetic anomaly maps give the essence of the crustal magnetic field that in turn provides useful geological inference and information about the magnetization of rocks in the subsurface. However, the magnetization depends on a large variety of parameters such as the composition of the crust, the heat flux, the age, the crustal thickness, the geological units, the stratification of the crust, etc. Some parameters of primary importance at large scale may be of secondary importance at smaller scales and conversely. Current efforts are being made to link these

geophysical parameters to the magnetization and to derive numerical simulators in order to model the magnetic crust in three dimensions. A better appreciation of the order of importance of each geophysical parameter involved in the observed lithospheric magnetic field at different spatial scales is the key to understand the magnetic structure and the thermal state of the Earth's crust, the uppermost part of the lithosphere, and its interactions with the deep mantle and surface processes.

Magnetic Anomaly Map, Global

Kumar Hemant Singh

Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India

Definition

Global Magnetic Anomaly Map is an international effort to integrate near-surface and downward-continued spaceborne maps of the magnetic anomaly field. These global maps are available as grids and find use in geologic and tectonic interpretation.

Introduction

Magnetic data have been collected from magnetometers towed by aircraft and ships for many decades now. Magnetic anomaly maps derived from regional airborne (*Magnetic methods, airborne*) and marine surveys are beneficial to our understanding of the subsurface structure, chemical composition, and geodynamics of the Earth's crust (*Continental crustal structure*) and lithosphere (Purucker and Whaler 2007). Maps derived from marine surveys were instrumental in the discovery of seafloor spreading and in the development of the theory of plate tectonics. Continental anomaly maps derived from aeromagnetic surveys interpreted with other geophysical information are used to delineate geologic and tectonic provinces and structures such as faults, dykes, and lineations (*Magnetic anomalies, interpretation*). These maps are also widely used, for example, in natural resource exploration, in estimating the thermal state of the Earth's lithosphere (*continental lithosphere: thermal structure*), and the

magnetic characterization (*Remanent magnetization*) of volcanic surfaces and deep interiors on both continents and oceans.

Satellite missions (*Magnetic methods, satellite*) have also made significant contributions in enhancing our knowledge of the Earth's magnetic field (c.f. Langel and Hinze 1998). Satellite data are acquired and processed in three-dimensional spherical coordinates; hence, the derived magnetic anomaly maps are on a global scale. The satellite data are measured typically 400–750 km away from the causative sources in the Earth's lithosphere, lack sufficient resolution of geological features smaller than 400 km in wavelengths, but find extensive use in studying the long-wavelength anomalies. In comparison, magnetic anomaly maps prepared from data recorded near the surface (~ few kms) and therefore near to the sources resolve short-wavelength anomaly features better (*Magnetic anomalies, interpretation*). There are, however, many geologic problems that could be better solved with the use of the self-consistent global magnetic anomaly maps that take advantage of the strengths of each data set while bypassing its limitation. For example, repeated rifting (*Continental rifting*) and movement of tectonic plates (*Plates and paleoreconstructions*) over hundreds of millions of years has made once adjacent landmasses drift (*Continental drift*) to a completely different region of the world. Reassembly requires consistently prepared magnetic anomaly maps over the entire globe consisting of both short and long wavelengths. The world digital magnetic anomaly map (WDMAM) derived from merging near-surface magnetic data and a global satellite model will aid evaluation of hypotheses about geologic origins of tectonic rifts, fracture zones that run across the continents, and tectonic history of many regions.

The WDMAM is the magnetic field defined on a grid of 3 arc-min angular grid resolution at an altitude of 5 km above the World Geodetic System 1984 (WGS84) reference ellipsoid (Fig. 1) (Korhonen et al. 2007). The world magnetic anomaly map is the first international collaborative effort to compile magnetic anomaly information on a global scale. The map is derived from more than 50 years of aeromagnetic, shipborne surveys over land and sea and supplemented by observations from earth-orbiting satellites. The global map shows the variation in the strength of the magnetic field (*Geomagnetic field, global pattern*) after the Earth's dipole field, and external field sources such as magnetosphere and ionosphere have been subtracted from the measured field. The remaining variations in the field (few hundreds of nanoteslas (nT)) are due to changes in the magnetic properties of the crustal rocks. In most places, the magnetic anomaly field is less than 1% of the main magnetic field of the Earth.

The magnetic fields derived in this map are internally consistent within the measurement domain, extending from the Earth's surface to satellite altitude (<750 km). The map

Magnetic Anomaly Map, Global, Fig. 1 The World Digital Magnetic Anomaly Map published by Commission for the Geological Map of the World (CGMW) in July 2007. The map is shown in Mercator Projection and is at an equatorial scale 1:50,000,000. (Courtesy: Korhonen et al. 2007)

comprises both the short and long wavelength anomalies from different sources. Short wavelength anomalies are derived from merging continental compilations and marine track line data. Long-wavelength features in this global map are based on a downward continued grid of the MF5 model, a model derived from CHAMP satellite magnetometer measurements. In oceanic regions where the data gaps exist, the digital age map of the ocean floor (Müller et al. 1997) was combined with the geomagnetic polarity time scale (Gee and Kent 2007; Kent and Gradstein 1986) (*Geomagnetic field, polarity reversals*) to estimate the total field anomaly at 5 km altitude.

The global magnetic anomaly map is available in both digital and print form. Two versions (A and B) of the map are available on DVD. The B version is shown in Fig. 1. The map is displayed in natural colors (red = positive values, blue = negative values) and produced from Generic Mapping Tools (GMT) (Wessel and Smith 1998). The A version differs in its handling of areas with data gaps, which are filled with the downward continued MF5 model. The map images and the DVD version of the WDMAM 2007 are available at <http://ftp.gtk.fi/WDMAM2007/>.

Early Developments

Magnetic surveys have been carried out on the land, sea, and from the air over all continents and oceans. The patchwork of aeromagnetic surveys over the continents and the tracks of oceanographic survey vessels across the oceans, together make up an enormous but distinct body of data. This incomplete and nonuniform coverage of near-surface data has recently been supplemented by reliable maps from Earth-orbiting satellites such as CHAMP (<http://www-app2.gfz-potsdam.de/pb1/op/champ/>). These satellite-derived models (*Magnetic method, satellite*) provide uniform coverage over the globe that can help resolve uncertainties in near-surface compilations produced by stitching together a disparate set of data. A new initiative was therefore required to combine these near-surface anomaly maps into a reliable global compilation and make it more accessible for geological mapping, educational purposes, and future research.

The original data is held by a large number of individual organizations around the world and, in some cases, is still commercially used and politically sensitive. In 1977, the International Association of Geomagnetism and Aeronomy (IAGA) (<http://www.ngdc.noaa.gov/IAGA/vmod/>) realized the importance of magnetic anomaly mapping for geologic and tectonic interpretation (*Magnetic anomalies, interpretation*) and noted the existence of numerous airborne and marine magnetic data. They began a concerted international effort to bring the global magnetic anomaly data set into place alongside other worldwide databases to maximize its use. Through a series of resolutions in 1979, 1995, and 1997, the

WDMAM task force was constituted by IAGA at the International Union of Geodesy and Geophysics General (IUGG) Assembly in 2003 to prepare a roadmap to complete the work. The job of the task force included (1) to catalogue existing data compilations that cover significant areas of the Earth; (2) to negotiate access to such data at a resolution sufficient for a global compilation; (3) to produce a preliminary paper map at the IAGA Assembly in Toulouse, France, July 2005; and (4) while addressing the main scientific and practical issues, to produce a digital magnetic anomaly map of the world for the 24th IUGG General Assembly, Perugia, Italy, July 2007.

The WDMAM task force urged various organizations and custodians of data to release nonsensitive versions of the classified or confidential aeromagnetic and marine track line digital data to the public domain for the WDMAM project. The organizations holding the data responded to the call and made near-surface data available for the first version of the WDMAM map. In June 2006, a call for submission of WDMAM candidate models was issued. In November 2006, five models were submitted for evaluation. Five teams at the National Geophysical Data Center (NGDC), NASA – Goddard Space Flight Center (GSFC), Geological Survey of Finland (GTK), GeoForschungsZentrum, Potsdam, Germany, and the University of Leeds, UK, produced candidate models for the WDMAM project (<http://projects.gtk.fi/WDMAM/project/>). After careful evaluation, the candidate model developed by NGDC was selected as a base map for representing anomalies over continents while the GAMMA model was selected for oceans. The first version of the official WDMAM was unveiled at the 24th IUGG General Assembly in Perugia, Italy, in July 2007 by the Commission for the Geological Map of the World (CGMW). United Nations Educational, Scientific and Cultural Organization (UNESCO) kindly supported and provided the funding for the printing.

Aeromagnetic and Marine Compilations

The first airborne surveys were done over the former Soviet Union in 1936, and the first maps of the total intensity were published at 1:2.5 million scale in 1974. These maps were later digitized and made available at one and three arc-minute grid resolution from the NGDC magnetic data archive (<http://ols.ndbc.noaa.gov/plolstore/plsql/olstore.prodspecific?prodnum=G01284-CDR-A0001>). More recently, another magnetic compilation for Russia compiled by the A. R. Karpinsky Russian Geological Research Institute is available as a 5-km resolution of the data grid (VSEGEI, <http://www.vsegei.ru/WAY/247038/locale/EN>).

The first ever North American continental-scale compilation was derived by merging magnetic anomaly maps of USA, Canada, and surrounding waters. The map was released in 1987 as a part of the Decade of North American geology.

The map had erroneous long-wavelength features, which revealed shortcomings and pitfalls in stitching together residual intensity maps reduced from measured data using different IGRF models (*Magnetic data, corrections and enhancements*). After correcting for these erroneous long wavelengths using Comprehensive Model (CM) (Sabaka et al. 2002), the improved maps for USA and Canada, in addition to the aeromagnetic compilation for Mexico, were combined to produce the revised North American magnetic anomaly map (Bankey et al. 2002). The Arctic and North Atlantic magnetic compilations including nearby landmasses were produced from a patchwork of shipborne and airborne surveys (Verhoef et al. 1996). Because the compilation had incorrect long wavelengths greater than 400 km, it was filtered before releasing the grid to the public domain.

Across the Atlantic, Wonik et al. (2001) prepared the first European compilation by merging magnetic data from north, west, and east Europe. The map retains the long-wavelength features but shows a poor correlation when compared with satellite data. However, there have been many developments in the last decade in preparation of high-resolution magnetic compilations from marine and airborne surveys. The Geological Survey of Japan compiled the grid for East Asia in 2002. The fourth edition, but a significant improvement over its previous version, the high-resolution magnetic anomaly grid for Australia and its surrounding oceans, was released (Minty et al. 2003). The noticeable feature of this map is its control over the long-wavelength anomalies which was achieved by flying long aeromagnetic traverses around Australia. The maps for China have also been recently made available in digital form by the Chinese National Aerogeophysics Surveys. Another map that was digitized for WDMAM project is a combined map for China, Mongolia, and Russia produced in 1995 by the Geological Survey of Canada. This map also had long wavelengths greater than 400 km corrected. In addition, the Antarctic Digital Magnetic Anomaly Project (ADMAP) provided the continental-scale compilation over Antarctica (Golynsky et al. 2001). The map was derived from merging aeromagnetic and marine data with the satellite magnetic data.

In addition to these data in the public domain, there have been efforts by industry-led consortia to produce maps for Africa, South America, and Middle East (http://www.getech.com/data/global_mag_margins.htm). Geological Survey of India also contributed the Indian magnetic compilation. Over oceans, NGDC's archives of track line data sets (<http://www.ngdc.noaa.gov/mgg/geodas/geodas.html>) were made available. In addition, the Project Magnet ocean traverse data were also available at http://www.ngdc.noaa.gov/geomag/proj_mag.shtml.

The details of the marine and airborne magnetic compilations that were used by the WDMAM task force to produce the candidate models can be found in Singh (2011) and at <http://projects.gtk.fi/WDMAM/project/contribution/>. The data density greatly varies between the northern and the southern

hemispheres. The coverage is especially sparse over oceans in the southern hemisphere where some of the marine track line data were not available for the project. Missing data are noted over parts of the Arabian Peninsula, India, East Asia, and many countries within Africa and South America. For processing the compilations, the datasets were grouped in three sets. The NGDC and Project Magnet marine and aeromagnetic track line data comprised the first set. Due to large errors and inconsistencies to be discussed later, the Project Magnet data was not used in the preparation of GAMMA candidate model. The second set included the gridded aeromagnetic and marine magnetic anomaly grids. The downward-continued MF5 model derived from the CHAMP satellite data made the third set. Of the track line profile data, the NGDC marine data and Project Magnet measurements together make 27 million points on 31,000 tracks. With scales ranging from country to continents, a total of 19 gridded data sets were made available.

The metadata information from the compilations when available shows the coverage to be in various projections and datums depending on their geographical representation on the globe. Hence, prior to applying any filtering or merging procedures, all grids were preprocessed and transformed from their local reference system to a common representation on the WGS84 global reference ellipsoid, using conversion formulas (Snyder 1987). The software, Oasis Montaj, Geosoft[®] was used in the preparation of the GAMMA model for upward-continuation of the data, while the Leeds model was produced on the ESRI's ArcGIS (www.esri.com).

Satellite Compilations

Several global models of the lithospheric magnetic field, based on satellite missions, have been produced in the last five decades (*Magnetic methods, satellite*). Although spherical harmonic analyses of data gathered at satellite altitude are typically used to compute the magnetic potential, they follow two different philosophies. The comprehensive approach (CM4), proposed by Sabaka et al. (2004), uses POGO, Magsat, Ørsted, CHAMP, and SAC-C measurements (*Geomagnetic fields, measurement techniques*) to derive a model that accounts for magnetic sources (*Geomagnetic field, theory*) from the Earth's main field to the external field sources in the ionosphere and magnetosphere and their temporal variations, including the crustal magnetic field component up to spherical harmonic degree 60. In contrast to the comprehensive approach, the second philosophy strictly focuses on the lithospheric field representation. This approach requires careful data selection and processing to clean the data from nonlithospheric sources (*Magnetic methods, satellites*). MF series of models are derived from CHAMP scalar and vector magnetometer measurements (<http://geomag.org/models/index.html>). The MF4 model used 4 years of

CHAMP data and is derived up to spherical harmonic degree 90. The map showed inconsistencies in the Polar Regions due to high data noise levels. The use of localized basis functions by Lesur and Maus (2006) led to the derivation of MF4x model which showed improvement in the lithospheric field at high latitudes. In 2007, the fifth generation of CHAMP models, MF5, was released (Maus et al. 2007a). MF5 extends to spherical harmonic degree 100 (400 km resolution) and showed a significant improvement, especially between 60° and 80° latitude, compared to previous models. After comparing the MF series of satellite compilations, the WDMAM committee recommended using the MF5 model for the preparation of candidate models. Recently, using only 3 years of CHAMP measurements, a high-resolution MF6 model was derived (Maus et al. 2008). The MF6 model is able to resolve the lithospheric magnetic field to degree 120, corresponding to 333 km wavelength. The MF6 model is also the first satellite-data-based global magnetic anomaly map to resolve the direction of oceanic magnetic lineations, which makes a helpful addition to the study of oceanic lithosphere (*Lithosphere, oceanic*) from space. The EMAG2 model uses the MF6 model to substitute the long-wavelength components. The last map produced by Maus and his group in the MF series of global lithospheric magnetic field models is MF7 (Maus 2010a). The model resolves crustal field up to spherical harmonic degree $n = 133$ which corresponds to 300 km wavelength on the Earth's surface. It is still the most widely used models, and the modeling strategy has remained largely unchanged from the previous version MF6. The model uses data from May 2007 to April 2010 when CHAMP satellite was in low-Earth orbit, which gives it the edge over its predecessors. In a recent development, LCS-1 model derived from CHAMP and Swarm data is able to resolve the lithospheric field up to spherical harmonic degree 185 (corresponding to 216 km horizontal wavelength) (Olsen et al. 2017).

Preparation of the Global Magnetic Anomaly Map

The NGDC candidate model (Maus et al. 2007b) uses the method of Least Squares Collocation (LSC) and line-leveling methods to generate a regular grid from irregularly spaced marine and aeromagnetic measurements. Other approaches for computing the candidate model include removal of a regional polynomial; iteratively adjusting a low-degree main field model for different epochs from each of the compilations; upward-continuation of the data to 5 km above the WGS84 ellipsoid; and finally knitting, merging, and filtering them together (Hamoudi et al. 2007). Long wavelengths (>400 km or spherical harmonic degrees ≤ 100) were removed from the individual compilations and replaced with the MF5 anomaly map of the total field

downward continued to 5 km altitude (Hemant et al. 2007). The following sections describe the preprocessing techniques and methods followed to derive the NGDC candidate model for WDMAM.

The WDMAM requires an accurate estimate of the crustal magnetic field on a 5-km angular resolution grid. Gridded data sets were mostly available in 5-km grid or even had a coarser resolution. In the case of track line data over the oceans, the resolution was variable (Singh 2011). Therefore, to prevent further loss of information during processing, all grids were decimated to 2.5 km angular resolution using the minimum curvature algorithm of GMT. Most of the compilations, in particular over the Northern Hemisphere, had overlapping regions. The compilations known to have higher accuracy or finer resolution were retained within overlapping parts by rejecting the coarser ones. In the process, the 15 arc-min GETECH data of South America and Africa were discarded whenever a higher resolution grid for the same region was available. Generally, the aeromagnetic surveys over the land are draped, meaning that they follow the surface topography at a constant altitude above the terrain. Thus, the derived compilations from these surveys follow topography. Therefore, to accurately process the altitude information with respect to a geoid, a topographic model of the Earth was used. The NGDC ETOPO-2 (<http://www.ngdc.noaa.gov/mgg/fliers/01mgg04.html>) surface elevation grid was linearly interpolated to the measurement positions and added to the terrain clearance of all draped surveys, to compute the measurement altitude above the geoid.

The continental-scale compilations used in WDMAM (Singh 2011) were produced after stitching together many regional aeromagnetic anomaly grids (Ravat et al. 2002). These regional surveys were flown at different times and, hence, used different International Geomagnetic Reference Fields (IGRF) models (*Geomagnetic field, IGRF*) to reduce the measured data. The patchwork grids were therefore prone to offsets and edge effects and mismatch in anomaly shapes and strengths across overlapping regions. They also had the potential to introduce spurious anomalies. These edge effects were corrected by subtracting a linear 2D trend from all smaller size grids.

It is well known that the genuine crustal anomalies of strengths ~ 500 nT can easily be contaminated by external field disturbances of amplitudes 100 nT. Thus, it has been a challenge to filter out short-wavelength noise from aeromagnetic and marine track line data. To filter these spurious signals, spatiotemporal variations of the magnetic field of strong but fast external field disturbances and those recorded by instruments onboard relatively slow-moving ships and aircraft are compared by computing the along-track derivative of the magnetic field residual. As a selection criterion, if the derivative exceeded 100 nT/km, 20 preceding and following measurement points on a track were removed. This selection

procedure removed about 3% of the marine track line profile data and 9% of the Project Magnet Data, which possibly were affected by external field disturbances.

Methods

Line Leveling of Data

In aeromagnetic surveys, inaccuracy in the measured positions of crossover points of acquisition, line-to-line differences in flying heights along adjacent tracks, and inadequate compensation for the magnetic field resulting from the aircraft lead to errors covering a region that extends beyond the line spacing in each direction (*Magnetic data, corrections and enhancements; Magnetic methods, airborne*). These errors are visible as linear anomalies parallel to the flight lines. If uncorrected, the computation of derivatives enhances these noise effects along the lines. This problem is common in acquiring aeromagnetic data. A common processing method to remove these errors is to line-level the data. A set of tie-lines, perpendicular to but spaced greater than that of the main survey lines, is normally acquired for line leveling. The line leveling procedure computes differences in the field values at the crossover points of the survey and tie lines, and corrections are applied to minimize these differences in the least-square sense (Reeves 2005).

The track line data, both marine and aeromagnetic, used for the WDMAM project is also likely to have this kind of problem. These track line data are first corrected for the main field and external fields. Additional navigational errors, instrument biases and disturbances from the unfiltered external field remain in the data causing uncertainty in the longer wavelength part of the magnetic field. The line leveling technique addresses these remaining errors in the track line data by minimizing the differences between adjacent or crossing tracks (Maus et al. 2007b).

The technique defines a correction function for each track given by

$$f_j(d) = \sum_{k=0}^{M_j} b_{j,k} \cos(\pi kd/X_j). \quad (1)$$

Here, X_j is the great circle distance from the first to the last point of the j th track and M_j is the number of parameters required for the estimation of the correction function of this track. The algorithm assumes $M_j = \text{trunc}(X_j/400 \text{ km}) + 1$ to correct for offsets with half-wavelength greater than 400 km. The choice of 400-km wavelength is based on the minimum wavelength the MF5 model is able to resolve. To minimize the misfit between all adjacent tracks and the differences of the track line profiles to the gridded data, the parameters $b_{j,k}$ are estimated from inversion. The line-leveling algorithm then minimizes the distance-weighted misfit between all

measurement locations. The weight function $W(r_{1,2}, z_1, z_2)$ used here is given by

$$W(r_{1,2}, z_1, z_2) = \max \left(0, 1 - \frac{1}{R_s} \sqrt{(r_{1,2}^2 + 2(z_1 - z_2)^2)} \right). \quad (2)$$

where R_s is the search radius, $r_{1,2} = ((x_2 - x_1)^2 + (y_2 - y_1)^2)^{1/2}$ is the horizontal separation, and z_1 and z_2 are the vertical coordinates of two locations 1 and 2 in the Cartesian coordinate system. In Eq. (2), the vertical separation $(z_1 - z_2)$ is up-weighted by a factor 2 to account for the greater variability of a potential field in the vertical than in the horizontal direction. The weights proportional to the distance from the margins of the grids were chosen. A value of 0.01 on the margin and 1.0 at 200 km inland were used. Although the line-leveling technique was effective in minimizing the misfit between adjacent tracks, it also introduced spurious anomalies with half-wavelengths larger than 200 km. However, these spurious long-wavelength anomalies were later replaced by those from MF5 model.

The implementation of the technique first required the decimation of 31,000 tracks of NGDC and Project Magnet data into 98,000 segments. These track line data were then line-leveled against each other by estimating 110,000 correction coefficients ($b_{j,k}$) from one grand inversion. This procedure also minimized offsets where tracks overlapped with gridded data. The segments that were affected by strong external field disturbances were removed when differences between two adjacent segments exceeded 550 nT and misfit against the gridded data exceeded 500 nT. The line-leveling and selection procedure further reduced the rms misfit between two adjacent segments from 380 to 130 nT and against the gridded data from 400 to 90 nT.

Least Squares Collocation

LSC is a scheme for interpolation by the weighted average of the measurements similar to the method called Kriging. The weighted averages are obtained in a minimum-variance sense. The technique of LSC has been used to solve a wide variety of problems in physical geodesy (Moritz 1980). It has been especially useful in certain satellite missions applications, such as satellite altimetry and satellite-to-satellite tracking. The LSC method is discussed in Langel and Hinze (1998) and has been applied by Maus et al. (2007b) to compute the NGDC global magnetic anomaly. Since locations of the measurement points in both track line and gridded data are not on a regular grid, one requires an interpolation procedure to estimate the field at regular grid nodes.

Following Moritz (1980), the LSC method estimates vector components of magnetic anomaly field values $\mathbf{b}$ on a predefined grid from a given set of vector magnetic measurements $\mathbf{c}$ at nearby locations. The vector of measurements, $\mathbf{c}$, is

defined as the sums of the true anomaly vector $\mathbf{a}$ plus an associated noise vector $\mathbf{e}$ (i.e., $\mathbf{c} = \mathbf{a} + \mathbf{e}$). To estimate the value of $\underline{b}$, covariance matrices are first computed as follows:

$$V_a = E(aa^T), \quad V_b = E(bb^T)$$

$$V_{b,a} = E(ba^T), \quad V_d = E(ee^T)$$

where E indicates the expected value. The collocation requires the estimation of the anomaly field $\underline{b}$ in the least square sense from

$$\underline{b} = V_{a,b}^T V_c^{-1} c, \quad (3)$$

where $V_{b,a} = (V_{a,b})^T$ and

$$V_c = E(cc^T) = V_a + V_d. \quad (4)$$

Here, it is assumed that $\mathbf{e}$ and $\mathbf{a}$ are uncorrelated, so that $V_{a,e} = V_{e,a} = 0$; and V_d is the error covariance matrix of measurement noise. The efficiency of the LSC method then lies in the computation of the covariance matrices V_a , V_b , and $V_{a,b}$ from properties of the true signal ($\mathbf{a}$) and the estimation of V_d from the properties of the noise.

For a Cartesian approximation of the data volume, Langel and Hinze (1998) suggest approximate correlation functions V_2 and V_3 between two locations at (x_1, y_1, z_1) and (x_2, y_2, z_2) of the form

$$V_2(r_{1,2}, z_1, z_2) = V_0 \beta \left(r_{1,2}^2 + (z_1 + z_2 + \beta)^2 \right)^{-1/2}, \quad (5)$$

where $\beta = r_c / \sqrt{3}$, and

$$V_3(r_{1,2}, z_1, z_2) = V_0 \beta^2 (z_1 + z_2 + \beta) \left(r_{1,2}^2 + (z_1 + z_2 + \beta)^2 \right)^{-3/2}, \quad (6)$$

where $\beta = r_c / 0.766$.

Here, the variance V_0 is a linear scale factor for the horizontal axis, while the correlation length r_c is a scale factor on the vertical axis. For magnetic anomaly fields, the use of one of these correlation functions for collocation depends on the variation of the function V_2 and V_3 with distance. Based on correlation functions for NGDC magnetic data, Australia and North America, empirically, it was determined that V_3 gives a better fit than V_2 . From V_3 , the values of V_0 and r_c are estimated to be 40,000 nT² and 15 km, respectively.

The value of $\underline{b}$ from Eq. (3) can then be estimated by computing the matrix $V_{a,b}$ given by (Maus et al. 2007b)

$$V_{a,b} = V_3(r_{a,b}, z_a, z_b), \quad (7)$$

and the matrix V_c from Eq. (4)

$$V_c = V_3(r_{1,2}, z_1, z_2) + E(ee^T), \quad (8)$$

are evaluated for all pairs of estimation (b) and measurement (a) locations. The error covariance matrix of measurement noise $E(ee^T)$ arises due to differences between adjacent tracks and between a track and a gridded data which undermine all other sources of errors in the data. After line-leveling, it was assumed the uncorrected difference is 25 nT and the error covariance matrix was set to 625 nT² for data pairs from the same set, and 0 nT² for data pairs from different sets. The line-leveled data were finally merged with the gridded data using the LSC method. This grid is called the final merged grid.

Merging Satellite Models

Finally, the NGDC candidate model was derived by combining the final merged grid with MF5 by computing the magnetic potential. As a first step, the magnetic potential of the line-leveled data was computed to spherical harmonic degree 120. The degree correlation (c.f., Langel and Hinze 1998) between this model and MF5 was shown to be about 0.6 at degree 100. This high correlation offered some validation of high-degree coefficients of MF5. The correlation suggests that CHAMP satellite data is able to resolve many small-scale features beyond degree 100 which could be crustal in origin. The power spectra of line-leveled data show excess power at low-degree (Singh 2011). This could be due to the remaining main field in the continental-scale grids and errors that are introduced in the long-wavelengths during stitching together the small-scale aeromagnetic surveys. At high degrees, the line-leveled data has 10% more power than MF5. Following a good spectral agreement between the line-leveled and MF5 model at degree 100, a sharp cutoff was used to substitute the long wavelengths of the near-surface data with the MF5 model. The substitution is carried out by subtracting the near-surface model to degree 100 from each grid cell and then adding the prediction from MF5. The final NGDC candidate model for WDMAM is a 3 arc-min angular grid of the total intensity anomaly at 5 km above the WGS84 geoid. The digital grid of the NGDC candidate for WDMAM also referred to as EMAG3 model is available at <http://geomag.org/models/wdmam.html>, and additional plugins can be downloaded from <http://www.getech.com/downloads/WDMAM> for visualization in NASA World Wind.

Other Candidate Models for WDMAM

There were four other candidate models for WDMAM. Two of those models, the GAMMA model produced by GeoForschungsZentrum, Potsdam (Hamoudi et al. 2007), and the Leeds model derived by the team at University of

Leeds, Leeds (Hemant et al. 2007), are published. These models are described next.

The Gamma Model

Most techniques were designed to improve the compatibility of the overlapping areas of neighboring grids. Hamoudi et al. (2007) applied different procedures to improve this incompatibility. These procedures are useful and easy to implement if only a few grids are used, for they require only first order estimation of improved long-wavelength values.

Prior to processing, the gridded and track line data were statistically analyzed to check for their self-consistency. For a pure anomaly field, one expects a symmetric distribution with zero mean. A skewed anomaly distribution not centered on zero possibly indicates some more or less severe contamination of other magnetic field contributions. In this respect, Russian, East Asian, and European compilations showed large anomaly intensity means. The standard deviation of anomaly distribution was usually between 100 and 200 nT for continents but could be as large as 930 nT on oceans. Oceanic magnetic anomalies of remanent origin have amplitudes larger than on continents, but such a wide distribution can only be explained by noise, bad tracks, and outliers in the data. Another criterion, based on the arithmetic sum, highlighted some bias in the marine, the Russian, Australian, and the East Asian compilations. These statistics were used to provide the available data and compilation with a quality flag.

The next procedure devoted to the analysis of data compatibility in the overlapping regions was based on Visual Inspection. By binning the data on a coarse grid, the spurious isolated points or track lines could be easily identified and manually removed. Other track lines, having consistent values but suspicious behavior, such as a few Project Magnet data crossing the African continent or possibly biased data offshore Senegal were removed. Some GETECH South American and African compilations showed unusual shapes like over Bangui. Considering that these grids were coarser than any others, it was decided to allow them a low weight in the final process. Similarly, the Indian grid based on repeat stations showed poor resolution, so magnetic map boundaries of Qureshy (1982) on the eastern coast were applied. The European grid showed unexpected geographical shifts by a few kilometers, in particular over Germany, so the grids were used for analysis only when no other data were available in that region. In general, most grids suffered from edge effects, possibly resulting from some kind of filtering at the last stage of their production. Some of these errors were identified but could not be systematically corrected due to lack of complete metadata information.

The third procedure was to carry out an arguably homogeneous correction for the core magnetic field. It has been customary to correct all aeromagnetic surveys with IGRF/DGRF core field models (*International Geomagnetic*

Reference Field, Magnetic Anomalies, Interpretations). Older surveys were corrected for more inaccurate core field models, particularly for those carried out at epochs when rapid core field variations were not yet identified (*Geomagnetic field, secular variation*). The core field correction was thus often followed by two-dimensional polynomial fitting or a Cartesian Fourier filtering. The DGRF models or polynomial fitting parameters were added to such old surveys whenever they were known, and a more recent core field model correction such as CM4 was used (Sabaka et al. 2004). When the core field models were unknown, a better solution was found by trials and errors. A DGRF core field model for different epochs was added to each of these surveys, and the CM4 was removed. When it improved the statistics (arithmetic mean, histogram of residuals), this correction was deemed fruitful. This procedure was not applied only for the Russian grid because it was outside of the CM4 time span (1960–2002). This procedure was shown to improve the data statistics by lowering the mean intensity anomaly toward zero and the continuity in overlapping areas between adjacent compilations and other artifacts caused by the different model biases. For countrywide compilations with a clear knowledge of the acquisition date, in France, Italy, and Spain, this procedure provided a better way to correct for secular variation between different compilations. For some other surveys, however, for which the exact epoch and corrections were poorly known, a regional polynomial adjustment was necessary. In order to avoid Cartesian distortion due to the Earth's curvature, a regional second-order polynomial from all grids in the WGS84 geographic reference was removed. This polynomial fitting was not applied to the Australian grid, where the long-wavelength control was good, or to compilations over geographic poles (Arctic and Antarctic grids), where the processing procedure was based on using Cartesian reference frame instead. After this correction, the grids were shown to have the expected properties characterizing the anomaly field with the average anomaly intensity and an arithmetic sum zero (Singh 2011).

The fourth step consisted of upward continuing of the data to the desired altitude of 5 km. Marine track line data sets were also upward continued to mitigate effects of the sharp transition at the ocean-continent boundaries. Grids smaller than 2000 km width, such as Argentina, Austria, Fennoscandia, Italy, France, Mexico, and Spain, were upward continued to 5 km altitude above the geoid without any further processing. However, larger compilations (>2000 km) were first split into 2000 × 2000 sq. km and upward continued individually. This dimension corresponds to the maximum size for which the Earth's curvature can be neglected (Nakagawa et al. 1985). After the upward continuation, the edge effects between adjacent grids were not significant.

The preliminary processing discussed earlier reduced the large discontinuities but did not fully remove them. The Grid-

knitting tool of GeoSoft was used to smooth the transition between adjacent grids. Some spurious wavelengths were created but were filtered out later. Merging large compilations with small compilations includes a risk because the adjustment is better constrained by the large compilation even if the small one has apparently a better quality. Before merging the grids, compilations with comparable grid sizes were generated and more weight was given to the grid showing the best statistical properties. Therefore, French, Italian, and Spanish grids were first merged together, followed by building a second grid, the Finland, Fennoscandian, European, and Austrian grids. These two new compilations were merged together and the grids from Russia, Eurasia, Middle East, Antarctica, and North America were successively added to the compilation. The remaining grids that did not overlap with the grids listed above were simply added in the corresponding geographical areas. This generated a $3' \times 3'$ global grid using GMT (<https://www.soest.hawaii.edu/gmt/>).

Finally, the spurious intermediate wavelengths introduced by the merging were filtered out by a spherical harmonic transformation. The wavelengths larger than those corresponding to spherical harmonic degree 100 were filtered out of the global grid and were replaced with those from the downward-continued MF5 model. The candidate model along with accompanying documentation is available at <http://www.earthref.org>.

The Leeds Model

To check for inconsistencies in the gridded data, the strength of total field intensities across the two overlaying grids is compared. Within the overlapping regions of Eurasia and Europe, total field intensities disagree in strength by 10–200 nT. At the grid boundaries, these intensities vary by 100–150 nT. These differences indicate possible errors in the long-wavelength content of the two grids. The discrepancies could also be attributable to the relative difference in the anomaly strength and resolution of the original grid. These differences are also observed between the Arctic and the North America compilations. Continental and oceanic compilations also show discontinuities in many regions.

For minimizing differences in the anomalies between various grids, a low-pass Gaussian filter with a cutoff wavelength of 400 km is applied in the 2-D space domain using GMT software. The cutoff wavelength is set to 400 km because the longer wavelengths are later substituted from the MF5 model, which is robust up to spherical harmonic degree 100 (~400 km). The filtered output is a long wavelength grid (>400 km) and strongly resembles a satellite-derived magnetic anomaly map. The short wavelength grid is computed by subtracting the long wavelengths from the original grid and shows finer details of the regional geology and structure of the crust (Singh 2011).

To analyze the systematic errors in the long wavelengths between adjacent overlapping grids, the difference in the long wavelengths is computed. A visual inspection shows differences in the anomalies exceeding hundreds of nT and often shows a lack of continuity across two or more grids. Because it is difficult to judge the trustworthiness of an overlapping long-wavelength grid, it was best suited to replace the filtered long wavelength with a reliable satellite model.

Techniques that merge two adjacent compilations often employ a weighted average of different-order surfaces such that the two adjoining maps are seamless within the merging area. These processes modify the grids within the overlaying regions and near the edges and alter the strength and pattern of anomaly features. In this process, anomalies are modified, or at times genuine crustal anomaly features are even entirely eliminated. The merging technique applied to merge short-wavelength magnetic anomaly data minimizes abrupt changes along boundaries of overlapping grids. Using the MOSAIC toolbox (<http://www.esri.com/>), the grid values within the overlapping regions were determined from Hermite Cubic functions (Franke 1982) and the short wavelength grids merged.

The short wavelength anomaly differences between grids vary substantially; hence, it is difficult to prescribe the order of precedence for merging. However, the quality of an individual compilation is also reflected in the long-wavelength differences. Therefore, the order of precedence of the grid merging was based on the difference between long wavelengths and the quality of the parent grid. Thus, the short-wavelength grids were merged in the following order: Australia, North America, Austria, Canary Island, East Asia, Eurasia, Europe, Arctic, Spain, Fennoscandia, France, Russia, Argentina margin and inland, South Africa, Antarctica, Italy, India, Middle East, Africa, and South America, NGDC track line and Project Magnet data. The grids were merged beginning with the highest precedence. The accuracy and reliability of the merged grid is assessed by investigating the effect of merging on the continuity of anomaly patterns across two or more grids and the effects on the anomaly shapes and strengths within and near the grid boundary. The differences for the merged European and Eurasian grid ranged from ± 100 to 200 nT and $< \pm 100$ nT for the remaining grid. A small difference of 8 nT was noted between Australian and East Asian grids indicating consistent anomaly patterns between the pair.

Finally, the total field anomalies of the short-wavelength merged magnetic anomaly map were added to the downward-continued total field anomaly of the MF5 model to produce the candidate model of the LEEDS-WDMAM (Singh 2011).

Earth Magnetic Anomaly Grid (EMAG2)

As an improvement to the WDMAM, track line data were added in the southern oceans, where the data gaps were significant. For WDMAM, these gaps in the ocean were filled with magnetic anomalies computed from ocean age model and geomagnetic polarity time scale. EMAG2 (Maus et al. 2009) was extrapolated into the unsurveyed areas using directional gridding based on the ocean age model of Müller et al. (2008). To further enhance the accuracy of the model over oceans, instead of using precompiled ocean magnetic anomaly grids, original track line data were used where available. Line leveling algorithm was the primary method to minimize crossover errors. The new Arctic compilation (Circum-Arctic Mapping Project) was used instead of the old Arctic compilation. A new crustal magnetic field model derived from CHAMP data, the MF6 model (Maus et al. 2008), is used for EMAG2 to correct the long wavelength anomaly field (wavelengths >330 km) replacing the MF5 model used for WDMAM model.

EMAG2 is 2 arc min grid defined at a height of 4 km above the geoid. The ocean data includes NGDC's GEODAS marine data archive, Antarctic Digital Magnetic Anomaly Project data (Golynsky et al. 2001), and the Project Magnetic Airborne data of the Naval Research Lab (NRL).

The line-leveling algorithm remains the same as described earlier. However, the search radius was reduced from $R_s = 100$ to 8 km in order to minimize the crossover effects in processing the track line data. In addition, the number of correction coefficients per track is now $N_i = \text{trunc}(X_i/300 \text{ km}) + 1$. These efforts reduced the crossover errors from 92 to 70 nT and reduced the RMS misfit to the merged grid from 121 to 97 nT.

Least squares collocation method requires estimation of the correlation function. No new correlation functions was computed for land areas as the gridded compilation remained the same. Notable changes for oceans, however, were made. For instance, for Australia, 100 m terrain clearance was used. Due to the inclusion of more accurate grids and original marine and airborne surveys, the assumed variance V_0 was reduced from 40,000 to 33,000 nT and the correlation length r_c from 15 to 14 km.

The methodology of LSC was slightly modified for EMAG2. The correlation analysis now considered the anisotropy of oceanic magnetic anomalies. Track line data, just the way it was processed for NGDC candidate model, were first divided into small windows but along the constant heading direction of the track. Next, for each track, the azimuth for every pair of measurement points was calculated and compared with the direction of the oceanic isochrons at the locations of both points. The pair was removed from further processing if they met one of the following criteria: (1) the azimuth of the isochrons was not well defined, (2) the azimuth

differed by more than 5° between the points, or (3) the topographic gradient between the two points exceeded 3%. The NGDC ETOPO-2 bathymetry values were used to compute the topographic gradient. This gradient could detect and remove the magnetic anomalies due to seamounts, which otherwise would appear as noise. The anisotropic correlation function was then computed in 10° directional bins; from 0° (parallel) to 90° (perpendicular, i.e., in the spreading direction) to the isochrons. This anisotropic correlation model allowed the LSC method to be used as a directional gridding algorithm.

From the analysis of covariance function in the isochron direction, it was noted that the function value reduced too rapidly. Furthermore, extrapolating the field far from a track line made the function reduce to zero. This produced erroneous stripes parallel to the track lines. To stabilize the covariance function, the correlation length was doubled when gridding the ocean areas. This made the anisotropy of the oceanic field in EMAG2 to be smoother than it perhaps is.

EMAG2 also suffers inaccuracies from the oceanic crustal age model due to errors in the estimated ocean isochrons. This error could easily have contaminated those estimated oceanic magnetic anomalies of EMAG2, where the uncertainties in isochron age are large. To reduce these uncertainties, empirically, the anisotropy factor was increased fourfold for all oceanic isochrons of age <140 Ma and a linear reduction to a factor 2.25 for ages >150 Ma was used. This procedure helped reduce the errors in EMAG2 within the oceans, in particular over the older crust.

For compiling the final EMAG2 grid, the portion of the original total field anomaly up to degree 120 is replaced by that of the MF6 model. A spectral comparison between the original and modified grids shows a slight discrepancy above degree 120. This is perhaps due to the leakage of long-wavelength power into shorter wavelengths. But the overall comparison generally validates the power content in EMAG2. The EMAG2 grid can be downloaded from <http://earthref.org/cgi-bin/er.cgi?s=erda.cgi;n=970> or from <http://geomag.org/models/EMAG2>.

New shipborne and trackline measurements were made available for the study of oceanic crust which led to the derivation of a significantly improved version of EMAG2, called the EMAG2V3. It represents magnetic anomalies at sea level in the ocean regions, and the wavelengths greater than 300 km were replaced with the CHAMP lithospheric field model, MF7 (Maus 2010a). The EMAG2V3 grid can be downloaded from <https://www.ngdc.noaa.gov/geomag/emag2.html>.

NGDC-720 Lithospheric Magnetic Model

In the last decade, successful attempts have been made to improve the resolution of the global magnetic anomaly

maps. The expansion of scalar magnetic potential into ellipsoidal harmonics in the least squares sense (Maus 2010b) led to the development of NGDC-720 model that represented anomaly of the total intensity of the field from degrees 16 to 719 corresponding to the variation of the wavelength from 2500 to 56 km. Newer versions of the models are available at <https://geomag.us/models/ngdc720.html>. The wavelengths larger than 330 km were

from the MF6 lithospheric field model (Maus et al. 2008).

Enhanced Magnetic Model

In the last half-a-decade, the Enhanced Magnetic Model (EMM) started replacing the NGDC-720 models. The

Magnetic Anomaly Map, Global, Fig. 2 The World Digital Magnetic Anomaly Map version 2.0 (WDMAM2.0) publicly released by 26th IUGG General Assembly in June 2015. (Courtesy: Lesur et al. 2016)

EMM2015 which extended to SH degrees 790 was able to resolve magnetic anomalies up to 51 km wavelengths, at least theoretically. The EMM2015 model was derived by merging ground magnetic measurements with the near-surface compilations and satellite data. An updated version, the EMM2017, was released on July 05, 2017, which included the European Space Agency's (ESA) three-satellite Swarm mission data. The EMM2017 is also an improved version of EMAG2V3 model and represents anomalies to Spherical Harmonic degree 790. The two models EMM2015 and EMM2017 differ primarily in oceanic areas owing to the different methodologies used in the derivation of their respective parent, EMAG2 and EMAG2V3, models. The EMM2017 is valid from 2000.0

to 2022.0 and has been developed primarily for the purpose of navigation. The model can be downloaded from <https://www.ngdc.noaa.gov/geomag/EMM/>.

World Digital Magnetic Anomaly MAP Version 2.0 (WDMAM2.0)

When the WDMAM project was conceptualized, it was envisaged to have WDMAM to be an ongoing project, with plans to produce updates of the map and grid every 4 years. As part of these updates, it was envisioned that more organizations will make additional data available for new versions of

WDMAM, in particular over regions where large data gaps exist. Toward this, Maus et al. continued to collect and process the data and produced their own maps, e.g., NGDC-720, EMAG2, and higher versions of the same. Thus, a need to derive the candidate models for WDMAM2.0 with the inclusion of data with prior agreement of the data owners was agreed upon.

After the release of the first version of the WDMAM (Korhonen et al. 2007), new aeromagnetic compilations over the continents and trackline data in the oceanic regions were released for the preparation of the second version of the WDMAM, or referred to as WDMAM2.0 (Table 1). Only one candidate model developed jointly by two independent groups, one at the GeoForschungsZentrum in Potsdam Germany, and the other at the Institut de Physique du Globe in Paris, France, was submitted for evaluation. The processing technique for the derivation of WDMAM2.0 (Lesur et al. 2016) was same as that followed for the derivation of the candidate GAMMA model (Hamoudi et al. 2007). All continental compilations were upward continued to 5 km above the WGS84 datum before merging them with the marine magnetic anomalies derived at the sea surface (0 km). The data gap over the marine areas has been filled up with the magnetization model of the ocean floor (Dyment et al. 2015). The

final merged grid is of resolution 0.05×0.05 degrees which are roughly equivalent to 5×5 km cell size on the Earth's surface. The resulting WDMAM2.0 grid (Fig. 2) represents 25,927,200 total intensity values computed relative to the CM4 field calculated for epoch 1990 and is derived up to SH degrees 16–800, of which the long wavelengths corresponding to SH degrees 16–100 are corrected using lithospheric field model GRIMM_L120 model (Lesur et al. 2013). The WDMAM2.0 was approved by IAGA during the 26th IUGG assembly in Prague, June 2015, and was officially released for its use by the scientific community (<http://wdmam.org/>).

The power spectra of EMM2017 and WDMAM2.0 models for spherical harmonic degrees 1–800 (degrees 1–790 in the case of EMM2017) are plotted in Fig. 3. A prominent low power is noticed in WDMAM2.0 model from degrees 1 to 15 compared to EMM2017. This is because the main field (*Geomagnetic field*, IGRF) has been removed in WDMAM2.0 model while EMM2017 retains it. Instead, the long wavelength anomalies from the Earth's lithosphere can be seen for degrees <15 , which otherwise remain hidden by the dominating main field of the Earth. The power from degrees 15 to 105 shows marginally higher power in EMM2017 compared to those of WDMAM2.0, which is

Magnetic Anomaly Map, Global, Fig. 3 Power spectra of the Enhanced Magnetic Model (EMM2017) and WDMAM2.0 models computed from spherical harmonic. (Courtesy: Lesur et al. 2016)

possibly due to unremoved main field in continental-scale grids and erroneous long-wavelength anomalies introduced in stitching together small-scale grids. Beyond the spherical harmonic degree 105, WDMAM2.0 shows consistently higher power than EMM2017, which becomes more pronounced beyond degree 250. This could perhaps be due to the addition of ocean magnetization model (Dyment et al. 2015) to fill data gaps in the marine region during the preparation of WDMAM2.0, something that is not a part of EMM2017 model. Again, considering the different data sources and their uncertainties and various data processing steps and corrections, the disagreement in power ($<0.1 \text{ nT}^2$) is judged small.

Summary

In summary, with methods discussed above, it will be possible to regularly update WDMAM model without excessive effort to reliably synthesize a map that accurately represents the world's magnetic anomalies. This would also require information on the long-wavelength field in order to continuously improve the representation of the world magnetic anomalies. The data from Swarm satellite mission of the European Space Agency (<http://www.esa.int/esaLP/LPswarm.html>) has already considerably improved the lithospheric magnetic anomaly maps by providing highly accurate measurements of magnetic field gradients and will likely further improve the long-wavelength anomalies in next generations of WDMAMs and EMMs. It is our hope that these global magnetic anomaly maps will enjoy widespread usage, and inspire further aeromagnetic and marine data holders to release the data, thus helping to produce maps having truly global coverage. Finally, the WDMAM and WDMAM2.0 would not have existed without the willingness of institutions to constantly revise and release their national scale compilation.

Magnetic data processing

Definition

Magnetic data are measurements of the magnetic field (generally of its intensity). Corrections of magnetic data are processing operations designed to remove unwanted features in the data. Enhancements of magnetic field data are

processing operations designed to preferentially accentuate the expression of a selected magnetization at the expense of others.

Introduction

Measurement of the earth's magnetic field is used in exploration geophysics as a remote-sensing method to investigate subsurface distributions of magnetization (see ► [“Magnetic Methods, Surface”](#)). The measurements require correction to eliminate artifacts and to remove the primary core field of the earth, thereby improving the expression of local field variations due to upper crustal magnetizations. These corrections are applied to produce clean and robust output suitable for interpretation (see ► [“Magnetic Anomalies: Interpretation”](#)). For specific interpretation objectives, enhancements are also applied to the data to increase the expression of selected sources at the expense of others.

The strong linkage between electricity and magnetic fields allows the development and calibration of magnetometers that supply absolute measurements of the magnetic field (see ► [“Magnetometers”](#)). Most processing corrections are designed to safeguard this integrity of data values and provide data suitable for input to modeling and inversion. Conversely, some enhancement operations distort the data and care must be taken to ensure that enhanced data is not used inappropriately.

Most magnetic field measurements are of the strength of the field, termed “total magnetic intensity” or TMI. Although these measurements are commonly treated as a scalar, it is important to remember that they are the amplitude of a vector, that the direction of that vector is also significant, and that in regions of strong fields the direction may vary across the survey area. The second most common form of magnetic field measurements are gradients of TMI, acquired by simultaneous measurement with two or more TMI sensors at fixed offsets (see ► [“Magnetic Gradiometry”](#)). Other forms of magnetic field data include measurements of the Cartesian components of the field and of the gradient tensor. Details of corrections and enhancement change only slightly between these different types of magnetic field measurements. The mathematical derivation of many correction and enhancement operators is presented in “Potential Theory in Gravity and Magnetic Application” (Blakely 1996) which provides an excellent basis to understand this topic. A brief review by Milligan and Gunn (1997) (http://www.ga.gov.au/image_cache/GA2486.pdf) is also useful reading.

Standard Magnetic Data Processing Corrections

Measurement of the earth's magnetic field provides a spot value at a specific time and location. Magnetic field data is

recorded together with ancillary information such as horizontal position, elevation, and time, as required for processing and interpretation. Corrections of data that are specific to instrumentation are an integral part of data acquisition and are not discussed in this topic. Common corrections in the processing of magnetic data include diurnal correction, leveling, IGRF correction, gridding, and reduction to pole.

Diurnal Correction

The earth's magnetic field is continuously changing (see ► [“Geomagnetic Field, Secular Variation”](#)), and this clearly presents a challenge in mapping spatial variations. Temporal changes of the magnetic field during the progress of a survey are generally termed “diurnal” variation, although this name more correctly describes field variations specifically at the 24 h rotation cycle of the earth. On normal “quiet” days the strength of the geomagnetic field varies across a range of approximately 30–100 nT. The amplitude and pattern of diurnal variation are functions of latitude, but vary sufficiently day to day that they must be measured at a fixed base station for subtraction from the field data. Surveys presenting the greatest challenges for diurnal correction are marine surveys away from suitable locations for a base station or that cover areas of substantial lateral variation in bathymetry or crustal conductivity (which influence diurnal variation through secondary induction fields). If a simple diurnal correction is insufficient, a spatial function can be generated from a distributed network of base stations incorporating time shifts according to the longitude of the base stations and the survey measurements.

There are also periods of rapid, high-amplitude variations in the magnetic field termed “magnetic storms” which follow periods of high sun spot activity. It is not feasible to accurately correct for field variations during magnetic storms and surveys are generally suspended during these periods.

Network Adjustment (Leveling)

Most magnetic field measurements are made sequentially from platforms moving along a profile. In particular, airborne magnetic surveys are generally flown on parallel, equally spaced flight lines (see ► [“Magnetic Methods, Airborne”](#)). To reduce errors arising from imperfections in diurnal correction and to compensate for any residual platform heading effects, a subset of lines, termed “tie lines,” is flown perpendicular to the main flight line direction at a spacing typically five or ten times larger than for the flight lines. The purpose of the tie lines is to provide a set of intersections with the flight lines that can be used for network adjustment or “leveling” of the data. Network adjustment progressively changes base levels, gradients, and curvatures of individual lines and line segments to minimize the misfit of flight line and tie line measurements across the network of intersection points.

Leveling errors are primarily manifest as sharp field variations along the axes of the flight lines.

Microleveling

The standard network adjustment of data is an empirical, least-squares optimization which leaves residual errors. Microleveling or “de-correlation” is a grid-based filtering process designed to attenuate residual level shifts between adjacent lines. These features are recognized as being parallel to the flight line direction and having a spacing related to the flight line spacing. Any valid magnetic field variations with similar characteristics will also be attenuated by microleveling (although any features parallel to the flight line direction are always of uncertain validity and difficult to interpret). Microleveling commonly has the objective of attenuating noise which becomes evident in the sun-shading of images, or to smooth “herring-bone” patterns in contour lines. Microleveling is also used to precondition data for subsequent enhancements that would otherwise include strong expressions of these residual leveling errors. Microleveling improves the quality of images of the magnetic field, but it also unpredictably attenuates field variations, and the output should not be used for modeling, inversion, or depth estimation studies.

Elevation Correction

Absolute elevation values are much less significant in magnetic field data processing than in gravity data processing (see ► “Gravity, Data to Anomalies”). The IGRF definition (see ► “Geomagnetic Field, IGRF”) includes elevation terms, but these only become significant over ranges much more substantial than those encountered in most surveys. More significant to the information content of magnetic field data is the elevation separation between the sensor and the shallowest magnetic sources. For this reason, airborne surveys are commonly flown on drape surfaces at a nominal terrain clearance. Rugged terrain clearly increases the problem of drape flying, and rugged areas are best flown on a compromise, smooth drape surface to reduce abrupt elevation steps from line to line. Rugged terrain also poses problems for leveling of data because of difficulties in achieving identical elevations on flight lines and tie lines at each intersection point. The most effective way to correct for these elevation differences is to re-project data from the sensor elevation onto a suitable smooth drape surface by using a set of equivalent sources (Emilia 1973) to invert the data, and then forward computing the field from those sources onto the reference surface.

Terrain correction, used extensively in processing gravity data, is rarely applied to magnetic field data. It is unusual for terrain to have a consistent magnetization such that the magnetic field of the terrain can be derived by any simple integration. Also, the ground surface is only an effective magnetization contrast over the top of strongly magnetized

bodies, and in situations of deep weathering or transported cover, the top of any strong magnetizations may be substantially beneath the ground surface. In areas of rugged terrain, the influence of terrain magnetization can sometimes be recognized, but these variations are generally less than those due to variations in separation between the sensor and the terrain. Typical elevation clearance variations include lower clearance over peaks and crests than over the flanking slopes, and increased clearance over deeply incised valleys. It is generally this variation in terrain clearance which carries the danger of incorrect geological interpretation. For instance, an increase in terrain clearance causes attenuation of magnetic field expressions of shallow sources which might be misinterpreted as due to zones of alteration and partial magnetite destruction.

Each magnetic field data channel should be linked to an elevation channel. For the primary field measurements, this is generally the sensor elevation determined from GPS altitude measurements. The smooth drape surface derived or implicit in leveling the magnetic field data is the effective elevation of that data for any modeling or inversion. With some airborne magnetic data, no elevation channel is supplied, and in these cases, the best option is to derive a synthetic elevation channel by interpolating the ground elevation (e.g., from SRTM data) onto the lines, adding the nominal terrain clearance reported for the survey, and then low-pass filtering. Another situation sometimes faced by an interpreter is to have only radar altimeter data available. The radar altimeter can be added to the terrain channel to recover sensor elevation, but before doing this, the radar data should be carefully inspected, as it may contain short-wavelength noise which needs to be smoothed, and possibly spikes or abrupt steps which must be eliminated.

De-culturing of Magnetic Field Data

The expressions of man-made features in magnetic field data used for geological studies are termed “cultural” anomalies, and the process of removing these anomalies is termed “de-culturing” the data. Anomalies may be recognized as being man-made by their sharpness, indicating that they are distinctly shallower than other field variations in the area, by distinctive characteristics, or by correlation with mapped man-made features. Automated search algorithms can be used to scan data for possible cultural anomalies, but generally removing cultural anomalies is an interpretive, labor-intensive effort. Removal of cultural features is best done from the primary data. More general removal of sharp variations in the data is known as “despiking.”

Gridding of Magnetic Field Data

Operations through to leveling of the magnetic data are performed on the primary located data, and key channels are appended to the data so that changes can be tracked through

the processing sequence. Once data has been leveled, the next process is generally to grid the data. Gridding is not a correction process, but is crucial to all subsequent processing, enhancement, display, and interpretation. Gridding interpolates the data from the measurement locations to nodes of a regular mesh, creating a new and fundamentally different construct of the data. Magnetic field data is generally gridded using minimum curvature operators to cell sizes of 1/4 or 1/5 of the line spacing. Minimum curvature operators (Briggs 1974) are generally implemented as multipass functions with control parameters which can be modified to adjust to different data sets. Minimum curvature is an appropriate imposition on magnetic field data as the magnetic field is continuous with continuous derivatives. More sophisticated gridding algorithms, such as anisotropic diffusion, can also be justified as supplying superior interpolation of the field, but minimum curvature is the current industry standard and is adequate in most situations. Gridding breaks down most readily for sharp anomalies due to small, shallow sources. This can occur either where the magnetized unit is particularly shallow or where it trends oblique to the flight line direction. In these situations, the anomaly due to a continuous magnetic unit may break down to a “string of pearls” or “bicycle chain” pattern (Fig. 1) because of the insufficiency of the gridding algorithm to interpolate that sharp field curvature from one

flight line intersection to the next. These artifacts restrict the use of sun-shading to highlight subtle features in the data and must be removed prior to any attempt to highlight those details by subsequent enhancement processing. These gridding artifacts can be attenuated by re-gridding at a coarser cell-size, or by using a redesigned gridding operator to produce a smoother, lower curvature grid. Interpretation of the depth to the top of a magnetic source is based primarily on the sharpness of curvature of magnetic field variations, and limitations in preserving the sharpest gradients through the gridding process mean that depths estimated from inversion or modeling of grid data may be overestimated, particularly for shallow sources.

IGRF Correction

Across survey areas of length several tens of kilometers or more, variations in the earth’s primary field may contribute significantly to the measured field variations. In order to emphasize more local field variations due to crustal sources, the International Geomagnetic Reference Field (IGRF), a global model of the earth’s magnetic field, is subtracted from the measured data. The IGRF is not a separation of field components from specific sources, but the long wavelength IGRF terms represent mostly core components and broad, lower crustal magnetizations. The IGRF is defined

Magnetic Data Enhancements and Depth Estimation, Fig. 1 Example aeromagnetic profile over a synclinal fold in the Frew River area of the Northern Territory of Australia (data courtesy of the Northern Territory Geological Survey). The TMI image on the right shows a “string of pearls” pattern. The top track of the profile data on the left

shows a vertical derivative enhancement of the measured TMI (black) and model computed TMI (red). The model was generated by inversion to match this filter enhancement. Profile modeling and inversion avoids the problem of grid artifacts

and published by the International Union of Geodesy and Geophysics (IUGG) (See entry ► [“Geomagnetic Field, IGRF”](#)).

Reduction to Pole (RTP) Transform

The external field of a magnetic body varies substantially as a function of the local geomagnetic inclination (see ► [“Magnetic Anomalies: Interpretation”](#)). The simplest relationship between the magnetic field and source magnetizations occurs at the geomagnetic poles where the field orientation is vertical (see ► [“Geomagnetic Field, Global Pattern”](#)). At the geomagnetic poles, induced anomalies due to steeply dipping bodies are essentially positive and are centered above the magnetization. The reduction to pole transform is a fast Fourier transform (FFT) filter applied to replicate the field variations expected in a vertical field. The RTP transform is unstable when applied to low geomagnetic inclination fields (this is generally perceived to be a problem at inclinations of less than 30°). The severity of the problems depends on data quality and sufficiency of sampling, and these problems arise in particular with any apparent North–South trending features in the data. Several methods can be used to overcome low inclination RTP problems. In one approach, the RTP filter can be distorted to reduce the instability. The output of the transform is not strictly valid, but may have the desired characteristics of a steep inclination field. Another approach is to use an equivalent source technique. The reduction to equator (RTE) transform also provides a partial alternative to RTP at low geomagnetic inclinations. The RTE transform shifts anomalies North–South to be directly above the source magnetizations, but the East–West elongation which is a natural characteristic of anomalies at low geomagnetic inclinations is slightly amplified. Note that RTP or RTE transforms should not be used in modeling or inversion studies, as forward modeling algorithms readily incorporate the local geomagnetic field direction (although RTP images may help to approximately locate bodies in starting models).

The commonly used RTP transform requires that the direction of magnetization be in the local direction of the geomagnetic field, and for bodies with substantial remanent magnetization (see ► [“Remanent Magnetism”](#)) in a different direction this transform is invalidated (see recovery of source magnetization direction from magnetic field data). If however the resultant magnetization direction (the vector addition of induced and remanent magnetizations) is known from palaeomagnetic studies, magnetic moment analysis, or inversions of the magnetic field data, then an alternative RTP operator can be used which allows for separate specification of the geomagnetic field and the magnetization direction (Fig. 2). All FFT filters have potential pitfalls, in part because of the fundamental assumption that the fields repeat infinitely beyond the sampled area. The FFT transform requires some processing to address level shifts between opposite edges of

the sample area and to pad the sample area with a smooth extrapolation. However well this is done, the output around the margins of the data is less reliable than in the center. This problem is of particular concern with the RTP transform, especially at the northern and southern edges of the data, and for longer wavelength field variations that are migrated furthest by the RTP transform.

The Pseudo-Gravity Transform

Gravity and magnetic fields are linked by the common fundamental theory of potential fields (see ► [“Magnetic Methods, Principles”](#)), as described by Poisson’s relationship (Baranov 1957). If the direction of magnetization is consistent, and if there is a constant ratio between density and magnetization, then the RTP magnetic field and the vertical gradient of the gravity field are identical. For any but the simplest geological system, there is no such reliable linkage between magnetization and density. Nevertheless, Poisson’s relationship provides a basis for converting a magnetic field to an equivalent gravity field expression. This transform includes an inverse vertical derivative operation which amplifies the expression of longer wavelength components of the field. The pseudo-gravity transform is sometimes used to apply analysis and processing techniques developed for gravity data to the magnetic field data but this must be done with care. For instance, the pseudo-gravity transform accentuates the longer wavelengths of the field but if the data from a small survey area is transformed those longer wavelengths are insufficiently sampled.

Enhancements of Magnetic Data

Enhancement of magnetic field data applies to any operation designed to highlight field variations due to a selected source of magnetization. These operations include application of various filters and also selection of display options such as histogram normalization and sun-shading.

Image Display of Magnetic Field Data

The display of magnetic field data is not an operation in the sense that it changes values of the data, but nevertheless it is highly significant in determining how the data is perceived and how easily geological information can be recovered from it. Magnetic field data generally has much sharper variations than gravity data across the same area, with much of the amplitude range in only a small subset of the data. For this reason, magnetic field data is often displayed using a histogram equalized color stretch devoting equal areas of the image to each color band. This form of imaging provides a much improved representation of detail across the complete range of the data. Histogram equalization does however have the drawback that it is difficult to appreciate the true

Magnetic Data Enhancements and Depth Estimation, Fig. 2 The top right image is of a TMI anomaly over the Black Hill Norite in South Australia which has strong remanent magnetization (data courtesy of the Department of primary Industries and Resources South Australia). The contour interval is 200 nT, and the outline is of the source body derived from a staged inversion of the TMI data using a resultant magnetization direction determined from magnetic moment analysis. The top right

image is of a standard RTP transform using an incorrect assumption that magnetization is in the geomagnetic field direction. The bottom left image is an RTP which correctly incorporates the resultant magnetization direction to produce a compact, positive anomaly centered over the source body. The bottom right image is an edge enhancement based on the tilt filter, applied to the resultant magnetization RTP. The maximum in this filter approximately matches the edge of the computed model

amplitude range of features or to compare the relative amplitudes of different features.

Another important enhancement tool in image display is the use of sun shading. This process involves the addition of shadows and highlights to an image to mimic the illumination of the data surface by a light source. These highlights and shadows reveal features of shorter wavelength and more subtle amplitude variation than can be easily recognized in the color mapping of the amplitude values. With a vertical light source, the highlights appear along the axes of minima and maxima. However, light sources are generally set to moderate or low inclinations to produce a stronger, directional enhancement of features trending perpendicular to the illumination direction. Illumination applied parallel to the flight line direction minimizes the expression of any residual leveling errors.

Vertical Continuation of the Field

The amplitude of a magnetic field above a source varies with elevation as an exponential function of wavelength. This relationship can be readily exploited with FFT filters to recompute the field at a higher elevation (“upward continuation”) or lower elevation (“downward continuation”). Upward continuation attenuates the field through an increased separation from the magnetization. Conversely, downward continuation towards the source or sources amplifies field variations. Upward continuation is inherently stable and acts as a smoothing filter, whereas the amplification of field variations due to downward continuation becomes unstable at depths approaching the source depth or shallower if there is any shorter wavelength contamination of the data. Methods including equivalent source computations can be used for continuations in which the input and/or output surfaces are

irregular. Upward continuation is useful for attenuation of fields from shallow magnetizations to improve focus on modeling of deeper sources as the effect of the filter can be directly compensated by changing the elevation at which the model field is computed.

Vertical Gradients of the Field

Vertical gradient (or alternatively named “vertical derivative”) filters preferentially amplify short-wavelength components of the field at the expense of longer wavelengths (Fig. 3). Vertical gradient filters are generally applied to gridded data using FFT filters and are therefore influenced by the characteristics of the gridding operator. Vertical gradient filters can also be applied to profile data on the assumption that the horizontal gradient measured along the profile is the only horizontal gradient. In some cases, this is a poor approximation but for highly elongate anomalies and with profiles approximately perpendicular to those anomalies the approximation may be acceptable. If, furthermore, the magnetic sources are shallow compared to the line spacing of the survey then there may be considerably more short-wavelength detail

in the profile data than is preserved through the gridding process. Vertical gradient profile filtering can be used to retain and enhance the shortest measured wavelengths during modeling and inversion by matching the outputs of the filter applied identically to the measured and computed fields (Fig. 1). The second vertical derivative is a more extreme enhancement of a magnetic field. As such, it provides a more distinctive amplification of fields from shallow sources, but simultaneously it is more sensitive to any short-wavelength artifacts in the data. In the event that a derivative of the field unacceptably accentuates noise or shallow magnetizations, the data can be preconditioned with a mild upward continuation before applying the derivative filter.

Bandpass and Matched Filters

The general relationship between depth of a source and the wavelength of its magnetic field can also be exploited to enhance the expression of sources from particular depths through bandpass filtering. Short-wavelength field variations can only be generated by shallow sources, so high pass filtering attenuates the expression of deep sources and

Magnetic Data Enhancements and Depth Estimation, Fig. 3 (All images are histogram equalized). The top left image shows TMI over the Frew River area of the Northern Territory of Australia (data courtesy of the Northern Territory Geological Survey). The bottom left image is of the vertical gradient of TMI. This enhancement reveals weak anomalies across the center of the image which are poorly imaged in the TMI data.

The top right image is the modulus of the analytic signal, which also enhances the expression of shallow magnetizations. The tilt filter image in the lower right is the most extreme enhancement and provides the best expression of weak, near-surface magnetizations across the lower gradient southern half of the area

conversely low pass filtering tends to attenuate the expression of shallow sources. However, bandpass filters rarely, if ever, provide a comprehensive separation of magnetic fields from different sources so their outputs are not suitable for modeling or inversion studies (unless the identical filter is applied to the forward computed model fields).

The power spectrum display of a magnetic field commonly consists of segments which approximate to straight lines, the slope of which is a function of the depth to the assemblage of sources whose field contributions dominate that part of the spectrum (Spector and Grant 1970). The inspection of a power spectrum can support selection of cutoff wavelengths for bandpass filtering, with the taper of the filter also very important. Filters should not truncate abruptly nor should they target too narrow a band of wavelengths. Size, shape, and depth extent of bodies also strongly influence their magnetic field power spectrum, and the analysis by Spector and Grant is valid only statistically and for an assemblage of bodies. With some bandpass filtering, the transform back into the space domain has been claimed to localize fields from sources at particular depths, with terms such as “depth slice” and “pseudo-depth slice.” These filters may produce images which are useful for interpretation but any claims that they effectively invert the magnetic field data to supply a 3D mapping of magnetization are untenable. Nor does fitting a straight line to a segment of a power spectrum prove the effective wave-number separation of field contributions from sources at any particular depth, as implied by classifying these filters as matched filters. The combination of spectral characteristics and spatial localization supplied by wavelet processing (see ► “Wavelet Analysis”) promises considerable advantages over FFT methods, and some wavelet processing methods are now being used, particularly for localizing edges of magnetization in multiscale edge detection.

Regional-Residual Separation

Potential fields are additive, and the magnetic field near the surface of the earth generally contains contributions from multiple crustal magnetizations. Separation of field variations from different sources is interpretive and nonunique, with no general analytic solution. One class of field separations is to remove local features of sharp curvature in the field (“anomalies” or “residuals”) from broader, lower curvature variations due to deeper or more distant sources (the “regional”), a process termed “regional-residual” separation. Regional-residual separation is most reliably performed in cases for which the fields to be separated have quite different characteristics; if the characteristics of the fields are similar, their separation becomes more interpretive and less certain. Regional fields are also due to geological structures, but which are too deep or distant to be of immediate interest in a specific project. For modeling

studies, the regional separation should be adjustable during the modeling, because a better realization of this separation emerges as the model is developed. The objectives and methods of regional-residual separation for magnetic fields are identical to those for gravity fields (see Gravity Data, Regional-Residual Separation) but the separations tend to be more easily made for magnetic data because curvature is higher for magnetic fields than for gravity fields and because small, shallow magnetizations create sharp magnetic anomalies distinctively different to the regional field while any gravity anomalies of those bodies may be too weak to be easily detected.

The Total Gradient (Analytic Signal)

The total gradient or analytic signal (more correctly the modulus of the analytic signal) (Roest et al. 1992) is a popular gradient enhancement used to highlight the distribution of shallow magnetization.

For compact or thin bodies, the modulus of the analytic signal peaks approximately over the center of the body and for wider bodies over their edges. It is only weakly sensitive to magnetization direction and indeed the two-dimensional case with only one horizontal gradient is independent of magnetization direction. The modulus of the analytic signal of TMI has much lower sensitivity to the inclination of the geomagnetic field than the original TMI data and provides a means to analyze low latitude magnetic fields without the concerns of the RTP operator. Source parameters such as depth can be estimated from statistics of the filter output but these advanced applications are more appropriately classified as interpretation rather than enhancement processing.

The Tilt Filter

The tilt filter (Miller and Singh 1994) has also become a popular enhancement.

The filter is computed from ratios of gradients and thereby retains no amplitude information. The filter output is defined at all places, but in areas of low gradient there is no signal to enhance so it is important that tilt images be interpreted with reference to the original data (Fig. 3). The tilt filter and analytic signal are both expressions of gradient ratios, and as such, there are clearly linkages between them in their tendency to amplify field variations from shallow sources, highlight the location of subvertical edges, and to indicate depth to magnetization contrasts according to their sharpness of variation.

The Normalized Source Strength (NSS)

The normalized source strength (Beiki et al. 2012) is derived from the eigenvalues of the magnetic gradient tensor. It highlights the distribution of shallow magnetization in much the same way as does the total gradient and in many situations the

Magnetic Data Enhancements and Depth Estimation, Fig. 4 (a) measured TMI anomaly at Ethabuka (data courtesy of the Geological Survey of Queensland), (b) TMI computed from elliptic pipe inversion model, (c) the NSS (blue contours) peaks over the center of the model but

the total gradient (red contours) peaks towards the edge of the model and is a less reliable estimation of the location of magnetization. (See recovery of source magnetization direction from magnetic field data)

two outputs provide similar results. The computational overheads of computing the NSS are at least an order of magnitude greater than required to compute the total gradient, but in some cases (according to the shape of distribution of the magnetization and the magnetization direction) the improved performance of the NSS may justify the additional effort it requires (Fig. 4).

Multiscale Edge Detection (“Worms”)

Ridge vectors of local maxima in the horizontal gradients of a magnetic field (worms) approximately map the horizontal location of steeply plunging magnetization contrasts. Applied following successive upward continuations of the field, these edge vectors are progressively more sensitive to magnetization contrasts at greater depths and sets of the vectors computed across a range of continuation heights provide an automated method of magnetic field analysis (Hornby et al. 1999). Multiscale edges defined by the wavelets have some affinities to different wavelength components separated in Fourier analysis, with the detail from shallow sources mostly carried in the small-scale edges, and broader, large-scale edges providing more information about deeper sources. Multiscale edge vectors are intrinsically linked to the analytic signal and tilt filter and to other curvature functions used to map source edges (Blakely and Simpson 1986; Grauch and Cordell 1987). Recovery of source information from potential fields as line vectors allows those sources and their spacing and orientation patterns to be investigated using vector analysis tools. Line vectors also provide advantage in

investigating similarities and differences between potential fields such as gravity and magnetics which are less easily summarized in comparison between images of those fields (Fig. 5).

Mapping Extreme Field Variations

Most magnetic field variations investigated in geophysical studies have amplitudes of less than a thousand nT and are measured in background fields of between 25,000 to 70,000 nT. Two consequences are that any misorientation of vector measurements is heavily penalized by accompanying error in the background field contributions and that the total field direction is consistent across anomalies permitting it to be treated as a potential field. In off-earth, low-field environments orientation error of vector measurements is greatly reduced and the total field direction varies across anomalies, disqualifying it for use with the enhancement and analysis tools described above. Similar considerations apply to extreme amplitude anomalies on earth. An iterative correction scheme can be used to convert measured total field data to vector-consistent magnetic field data for use with FFT enhancement and analysis tools (Clark 2013). The analysis produces grids of vector components of the field from which field declination and inclination grids can be derived (Fig. 6). Forward modeling algorithms used to compute magnetic fields provide the measured field directly and the field declination and inclination can be independently estimated from vector components computed from those models (Fig. 7).

the inversion model and which match the equivalent outputs shown in Fig. 6 (b) and (c) derived independently from the measured TMI to vector-consistent TMI transform

Analytic Derivation of Magnetic Source Parameters

Nonuniqueness in interpreting a distribution of magnetization from study of a measured magnetic field precludes any definitive analytic solution. All source depth estimation is dependent on an assumed source geometry model or equivalent statistic such as the structural index. Voxel models without shape constraint are unsuited to source depth estimation and generally require an imposed bias such as a depth weighting function to select a preferred model. Parametric models are better suited to recovery of source statistics but are dependent on the model characteristics providing a valid representation of the magnetization. Parametric inversion provides a powerful analysis of the sensitivity with which various model characteristics can be recovered.

Compact bodies have intrinsically low sensitivity in estimation of depth to top. Figure 8 shows three co-centered magnetic spheres which produce an identical magnetic anomaly. Anomaly amplitude is a function of the magnetic moment (the product of volume and magnetization) but not of the individual magnetization and volume values. Although the three spheres produce an identical anomaly, there are significant differences in depth to their tops. This is an extreme example of the ability of one parameter to compensate for variation of another. Similar but inexact relationships are also shown in Fig. 8 for narrow vertical bodies of large depth and

strike extent (“dykes”). The magnetic anomalies of these bodies depend on only three parameters: width, depth to top, and magnetic susceptibility. There is considerable sensitivity of the magnetic anomaly to variation in depth to top where that is the only parameter changed (Fig. 8b), but if thickness and magnetic susceptibility are also allowed to change the sensitivity to depth is severely reduced (Fig. 8c).

Automatic mapping of source magnetization distributions has been one of the most prolific subjects of geophysical publication over many years. Those methods that have achieved widespread acceptance and use can mostly be classified into a small number of groupings, namely, Wener deconvolution, Euler deconvolution, the Naudy method, and the source parameter imaging (“SPI”) method. The fundamental assumptions of the various methods are necessarily similar, and in many cases identical, but nevertheless there are some practical differences which might lead to advantages in applying certain methods in certain circumstances. In all cases, the key factor for successful application of automated source detection and parameter estimation is the suitability of the geology. If the geology provides discrete, homogeneous, well-separated, moderate to strong magnetizations in simple and predictable geometries then any of the automated source estimation methods should work well. If however the geology results in irregular and indistinct distributions of magnetization, then there is no basis for the successful application of any of the methods and they can only lead to fictitious and

Magnetic Data Enhancements and Depth Estimation, Fig. 8 (a) Co-centered spherical magnetizations of identical moment but different radius and depth to top generate identical anomalies, (b) TMI anomalies over identical tabular bodies of large depth and strike extent with -20%

and $+20\%$ depth offset, (c) TMI anomalies of the depth-offset bodies with susceptibility and thickness adjusted to minimize least-squares difference between the anomalies

misleading results. This gives rise to a common dilemma in source depth estimation; whether to set strict quality conditions and accept just a few solutions of apparently high validity, or whether to relax the quality conditions to generate a more comprehensive set of solutions of less certain validity. In practice, validity of solutions is commonly evaluated from their quality coefficients, by clustering of solutions and their internal consistency, or simply by visual inspection and judgment as to whether the magnetic field anomaly the solutions are derived from is reliable and suitable. The ability to rapidly generate source parameter estimates from automatic or semi-automatic methods is in part offset by the time and discretion required to evaluate and interpret the reliability and usefulness of those results. All automated source depth estimators also have in common that they are dependent on the quality and sufficiency of the magnetic field data. A concise review of magnetic depth estimation methods and practical advice on their application is given by Li (2003).

The Werner Method

The Werner method of automatically generating magnetic source solutions from profile magnetic field measurements (Werner 1953) solves for simple geological structures by solution of linear equations applied to profile data sampled within a moving window. The equations are specified for bodies of nominated structural index and can be solved either for single profile data or can be extended to a three-dimensional multiple source analysis.

The Naudy Method

The Naudy method (Naudy 1971) is an elegant approach to finding and solving for magnetic sources from analysis of profiles of magnetic field data. As a window is moved along a magnetic field profile, the data is split into symmetric and asymmetric components about the center of the window. Firstly, the reference anomaly is computed for a target body of the nominated type and specified properties and a correlation coefficient is derived between that target curve and the processed field data curves. A coefficient value beyond a set threshold flags a possible solution, which is then fed to a second stage inversion process which searches for the optimum source parameters. A key advantage of the Naudy method is that it supplies bodies which can then be delivered into a modeling package for more detailed testing against the data they were derived from, and as starting models for more interpretive studies. The Naudy method has been extended by Shi (1991) to run on the vertical derivative (Fig. 9) with advantages that the derivative is more sensitive to the top of the body and does not require definition of the background field.

Euler Deconvolution

Euler deconvolution solves for Euler's homogeneity equation within a moving window assuming that the field variation within the window is due only to a single source body with a defined structural index. Reid et al. (1990) extended the analysis to a two-dimensional window of grid data. Sources of error are that the structural index value used may be

Magnetic Data Enhancements and Depth Estimation, Fig. 9 Naudy AutoMag analysis tuned to the vertical derivative over Gairdner Dykes (lower track). Data is from the Gawler Craton Airborne Survey (courtesy of the Geological Survey of South Australia) with a

profile of computed (red) and measured (black) TMI and vertical derivative channels and (top track) the similarity coefficient for which minima below a set threshold trigger source solutions as seeds for the bodies (shown in magenta) that are subsequently fine-tuned with inversion

inappropriate and that the field variation within the window may be due to more than one source. As a consequence, the solutions themselves require interpretation. There have been numerous adaptations of the method to try to estimate the appropriate structural index for each solution and to analyze clusters of solutions. Euler deconvolution has also been extended to application with the modulus of the analytic signal and to solution for multiple sources. Other implementations of the Euler homogeneity equation to derivatives of the magnetic

field which supply estimates of structural index as an integral part of the analysis are termed “extended” Euler methods. Nabighian and Hansen (2001) have shown that the extended Euler method is a unification of Euler deconvolution and the Werner method. Thurston and Smith (1997) applied Euler’s homogeneity equation to expressions of the complex analytic signal in a method termed source parameter imaging (SPI) which recovers source estimates for dipping 2-D contacts and dipping 2-D thin sheets from gridded magnetic field data. This

Magnetic Data Enhancements and Depth Estimation, Fig. 10 Example sweet-spot depth inversion from the Gawler Craton Airborne Survey (courtesy of the Geological Survey of South Australia). The grid traverse (left) was selected in map view to sample 3 TMI

anomalies (right). Three flat-topped source bodies located beneath the anomalies are strike and azimuth adjusted to match the anomaly and the profile data segments are inverted to generate three source depth estimates

method requires recovery of higher derivatives of the magnetic field, and ultimately it is the validity of those higher derivatives in the presence of noise and processing artifacts that determines the usefulness of the method.

Targeted (“Sweet-Spot”) Inversion

Automatic source analysis does not recover the full value of magnetic survey data and is a poor justification for substantial decisions such as the location and design of boreholes. The distribution of geological information in magnetic field data is highly irregular and can only be recovered above locations of separated moderate or strong magnetization contrasts. These locations can be selected manually by an interpreter or can be generated automatically as profiles through anomaly peaks perpendicular to the local trend of the field. Computation-intensive inversions of the resulting small data sets find optimum models of selected type. For estimation of depth to the top of magnetization, the most appropriate models have horizontal top faces (Fig. 10) because unconstrained curvature of the top face substantially increases the depth range across which solutions can be found to fit the data. The sweet-spot method supplies high quality magnetic source depth estimates but is still bound by fundamental nonuniqueness constraints.

Summary

A substantial toolbox of methods exists to process and enhance magnetic field data, and these capabilities are

continuously being extended as computing power and speed increase. Most of the methods require careful inspection of the data to select optimum parameters and to detect any undesirable characteristic in the outputs. Enhancement operations are best selected and designed for a specific interpretational objective, and different enhancements can be applied to the same data for different objectives. Operations such as gridding and visualization are an integral part of processing and enhancement and also require careful attention to avoid misrepresentation of data. There is an arbitrary delineation between methods such as multiscale edge detection described here as an advanced enhancement and automatic depth estimation such as Euler deconvolution which attempts a marginally greater level of discrimination and represents transition into interpretation. The current trend of automatic source depth estimation is towards ever greater sophistication using high-order derivatives of the field, but these methods place ever greater stress on the validity of the data such that the derived parameters require careful evaluation. For situations requiring greater confidence in the results, automated depth analyses can be replaced with interpreter-controlled processes such as sweet-spot inversion.

Magnetic Domains

Susan L. Halgedahl

Department of Geology and Geophysics,
University of Utah, Salt Lake City, UT, USA

Definition

Magnetic domain	A magnetic domain is a region in which the magnetic spins of atoms or molecules are aligned. Many magnetic particles consist of two or more magnetic domains, each of uniform magnetization separated by narrow zones called domain walls, in which the spins change orientation from one domain to the next.
NRM (natural remanent magnetization)	The magnetic moment (per unit volume or per unit mass) acquired by a rock in nature.
TRM (thermal remanent magnetization)	The magnetic moment acquired by a rock as it cools from the Curie temperature in the Earth's field.

Introduction

The existence of a paleomagnetic record attests to the ability of magnetic minerals in rocks to preserve their natural remanent magnetizations over geologic time. The building block of *Remanent Magnetism* is the magnetic domain, a region where the magnetic spins are aligned in the same direction. In the early days of paleomagnetism, it was thought that the stable components of natural remanent magnetization (NRM) mainly resided in extremely small magnetic mineral grains that occupied the single-domain (SD) state. However, it is now recognized that, due to their very small size and scarcity, SD particles may not be the major carriers of NRM in many rocks. Instead, it is more likely that much of NRM is carried by grains that, by virtue of their larger sizes, are subdivided into several domains (Fig. 1). Adjacent domains are separated by domain walls, the transition regions where magnetic spins change direction from one domain to the next.

Remanences carried by SD assemblages can be highly stable, because destroying the remanence requires rotation of the particles' magnetic moments across strong energy barriers. In contrast, remanences carried by particles with two or more domains usually owe their stability to pinning of walls at crystal defects; these energy barriers are overcome more easily than those controlling SD grains. But another necessary criterion for paleomagnetic stability over geologic time is that a grain's overall domain state resists drastic

Magnetic Domains, Fig. 1 Illustrations of (a) a multidomain cube containing four domains and (b) a single-domain cube of uniform magnetization

reorganization caused by the changing physical/chemical conditions affecting the rock, such as moderately elevated temperature, moderate pressure, and some chemical alteration. For this reason, we discuss both theories and experiments to investigate how domain structure depends on grain size, applied field, and temperature in natural magnetic minerals and their synthetic analogues. (See detailed treatments of these subjects in standard texts such as Chikazumi (1964), Cullity (1972), Stacey and Banerjee (1974), and Dunlop and Ozdemir (1997)).

Classical Models of Magnetic Domain Structure

Exchange Energy

Models of magnetic domain structure are based on three energies: exchange energy, anisotropy energy, and magnetostatic energy. Magnetostatic energy is the fundamental reason why particles subdivide into two or more domains because, in so doing, this energy is reduced. However, this subdivision carries an energy “price”: the energy of domain walls. In most classical theories, the first two energies above make the largest contributions to the surface energy of the wall. From seminal calculations, Heisenberg (1928) predicted the existence of the exchange interaction, which determines whether adjacent magnetic spins are aligned parallel or antiparallel with respect to each other in a specific substance. In a relatively few materials, this interaction leads to a configuration of lowest energy when neighboring spin vectors are aligned. This gives rise to the rare phenomenon of spontaneous magnetization (M_s) and magnetic remanence. Such materials possess a Curie temperature, above which spontaneous magnetism vanishes, because (a) thermal agitation disrupts the alignment of adjacent spins, and (b) thermal expansion of the lattice increases spin–spin distances and thus weakens the exchange interaction.

Magnetic Anisotropy Energy

Magnetic anisotropy causes magnetic behavior to depend on the direction in which it is measured. In magnetite, for

example, magnetocrystalline anisotropy results in a lower external field being required to saturate a crystal along the $\langle 111 \rangle$ directions than along $\langle 100 \rangle$. Magnetocrystalline anisotropy arises from the coupling between spins and orbits of the electrons, so that work is required to rotate spins out of the directions of lowest energy (“easy” directions). “Easy” and “hard” directions depend on the specific material and its crystal structure. In cubic materials such as magnetite, the easy directions are along $\langle 111 \rangle$, whereas in iron $\langle 100 \rangle$ are easy directions (e.g., for more comprehensive discussions, see Chikazumi (1964); Cullity (1972)).

Also due to spin-orbit coupling, the lattice of a ferromagnetic material will spontaneously strain below the Curie temperature. The inverse effect is that external stress and/or variable internal strain can rotate the spontaneous magnetization away from the easy direction given by crystalline anisotropy. Depending on the material and the stress direction, applied stress may cause M_s to rotate either toward the stress axis or toward the direction perpendicular to the axis of stress.

Magnetostatic Energy

Magnetostatic energy is the work, per unit volume, required to assemble a population of magnetic “free poles” into a particular geometric configuration. A simple but highly relevant case was addressed by Kittel (1949), who analyzed a semi-infinite plate of thickness L containing lamellar domains of uniform width D , with spontaneous magnetizations normal to the plate surface (Fig. 2). Kittel obtained $E_m = 1.705 M_s^2 D$, where E_m is the magnetostatic energy, per unit area of plate surface (erg/cm², in cgs). Kittel’s calculations were refined by Rhodes and Rowlands (1954), who addressed finite, rectangular grains. Their results produced “Rhodes and Rowlands” functions, which yield the total magnetostatic energy of rectangular grains of specified axial ratios.

Energy and Width of the Domain Wall

A domain wall is the transition region where the spontaneous magnetization changes direction from one domain to the next, so that each domain is distinct from a wall. (Micromagnetic theories relax this assumption and will be discussed in later.) The two most important energies contributing to the wall’s energy and width are exchange energy and anisotropy energy, the latter due either to magnetocrystalline anisotropy or stress. The magnetostatic energy of the wall itself also plays a role; this energy was first analyzed by Amar (1958) and grows especially important when the wall width approaches that of the particle.

In the simplest models, spins in a wall reach an equilibrium configuration when magnetic anisotropy and exchange energies are balanced. For the 180° “Bloch” wall shown in Fig. 3 in which spins rotate through 180°, the energy per unit area of wall surface is $E_w = 2\pi (AK)^{1/2}$, where K is the

Magnetic Domains, Fig. 2 Illustration of the semi-infinite, magnetized plate of thickness L , whose magnetostatic energy was calculated by Kittel (1949). The plate contains domains of identical width D , with magnetizations perpendicular to the plate's surface. Walls are assumed to be infinitely thin

Magnetic Domains, Fig. 3 Illustration of spins in a 180° Bloch wall. θ is the angle between a spin and the easy axis of magnetization ϕ is the angle between adjacent spins

magnetic anisotropy constant due to magnetocrystalline anisotropy and/or stress and A is the material's exchange constant. Note that a submicroscopic change in either A or K can change the local wall energy. Such local changes constitute "wall pinning" sites, where wall motion is impeded by either an energy barrier or an energy trough. The width of a 180° wall is $\delta_w = \pi (A/K)^{1/2}$. In magnetite, values predicted for E_w and δ_w are approximately 0.9 erg/cm² and 0.3 μm , respectively (e.g., see Dunlop and Ozdemir 1997).

Domain Width Versus Grain Size

For the magnetized plate illustrated in Fig. 2, domain width D can be calculated for the lowest energy state by minimizing the sum of magnetostatic and wall energies per unit volume of material: this gives the half-power law $D = (1/M_s) (E_w L / 1.705)^{1/2}$ (Kittel 1949).

Magnetic minerals in rocks, however, rarely grow as thin platelets. Moskowitz and Halgedahl (1987) calculated the number of domains versus grain size in rectangular particles of $x = 0.6$ titanomagnetite ("TM60": $\text{Fe}_{2.4}\text{Ti}_{0.4}\text{O}_4$) containing planar domains separated by 180° walls. Magnetostatic

energy, including that from the walls' moments, was accounted for (Rhodes and Rowlands 1954; Amar 1958), and it was assumed that grains occupied states of absolute minimum energy. Their calculations yielded two principal results: (1) particles encompassing a wide range of grain sizes could contain the same number of domains, and (2) a plot of N (number of domains) versus L (grain thickness) could be fitted well by a power law $N \propto L^{1/2}$. It follows that domain width D also follows a half-power law in L . Thus, the general type of functional dependence of D on L is the same for both finite, rectangular grains and semi-infinite plates.

Single-Domain/Two-Domain Transition Size d_0

Grains containing only two or three domains can rival the remanences and coercivities of SD grains, and such particles are often referred to as being "pseudosingle-domain" (PSD). A particle may favor a two-domain over a SD state because the magnetostatic energy associated with two domains is much lower than that for saturation. However, below d_0 the energy price of adding a wall is too great to result in a state of minimum energy. At d_0 , the total energy of the two-domain state and the SD state are equal. PSD grains can be common in many rocks and, in terms of interpreting rock magnetic behavior, it is important to know the grain sizes corresponding to the onset of PSD behavior in various magnetic minerals.

This transition size depends on the material's magnetic properties, its state of stress, the particle shape, and temperature. Moskowitz and Banerjee (1979) calculated total energies of SD, two-domain, and three-domain cubes of stress-free magnetite containing lamellar domains at room temperature. Magnetostatic energy of the walls was included in their calculations (Amar 1958). They obtained $d_0 \approx 0.08 \mu\text{m}$. Similar calculations for TM60 by Moskowitz and Halgedahl (1987) yielded $d_0 \approx 0.5 \mu\text{m}$ for unstressed particles at room temperature. Raising the stress level to 100 MPa shifted d_0 upward to 1 μm .

Domains and Domain Walls Near Crystal Surfaces

In relatively thick crystals, domains and domain walls may change their geometric styles near and at crystal surfaces, in order to lower the total magnetostatic energy with respect to that of the "open" structure shown in Fig. 2. The particular style depends largely on the dominant kind of anisotropy, as well as on the relative strengths of magnetostatic and anisotropy energies. When $2\pi M_s^2/K \gg 1$ in a uniaxial material, prism-shaped closure domains bounded by 90° walls may completely close off magnetic flux at the crystal surface (Fig. 4a). Because closure domains greatly reduce magnetostatic energy, the "body" domains can be several times broader than predicted for the "open" structure.

When $2\pi M_s^2/K \ll 1$ in a uniaxial substance, a large amount of anisotropy energy results when M_s is perpendicular

Magnetic Domains, Fig. 4 Three styles in which domains and domain walls may terminate at a crystal surface. (a) Prismshaped surface closure domains at the surface of a material which is either uniaxial, with $2\pi M_s^2/K \gg 1.0$, or cubic, such as iron, whose easy axes are along $\langle 100 \rangle$. Here, 90° walls separate closure domains from the principal “body” domains that fill most of the crystal. Arrows indicate the sense of spontaneous magnetization within the domains. (b) Wavy walls at the surface of a uniaxial material with $2\pi M_s^2/K < 1.0$. Waviness dies out with increasing distance from the surface. (c) Prism-shaped closure domains at the surface of a cubic material, such as magnetite, whose easy directions of magnetization are along $\langle 111 \rangle$. Closure domains and body domains are separated by 71° and 109° walls

to the “easy” axis, making the style of surface closure shown in Fig. 4a energetically unfavorable. Instead, walls that are planar within the body of the crystal can become wavy at the surface (Fig. 4b). In extremely thick crystals, wavy walls can alternate with rows of reverse spikes. These elaborate surface domain structures lower magnetostatic energy by achieving a closer mixture of “positive” and “negative” free magnetic poles (e.g., see Szymczak 1968).

Large crystals governed by cubic magnetocrystalline anisotropy also reduce surface flux through prism-shaped closure domains at the surface. When $\langle 100 \rangle$ are easy directions, as in iron, closure domains are bounded by 90° walls (Fig. 4a). When $\langle 111 \rangle$ are easy directions, as in

magnetite, closure domains are bounded by 71° and 109° walls (Fig. 4c).

Temperature Dependence of Domain Structure

Understanding how domain structure evolves during both heating to, and cooling from, the Curie point is crucial to understanding the acquisition and thermal stability of thermal remanent magnetization (TRM). If the number of domains changes significantly during cooling from the Curie point in a weak field, it is reasonable to hypothesize that TRM will not become “frozen in,” or blocked, until the overall domain structure reaches a stable configuration.

According to Kittel’s original model (Fig. 2), grains will nucleate (add) domain walls and domains with heating in zero field, if the wall energy drops more rapidly with increasing temperature than does the magnetostatic term. Energy-wise, in this first case, a particle can “afford” to add domains with heating. Conversely, during cooling from the Curie point, a grain will denucleate (lose) domains and domain walls if wall energy rises more quickly than does the magnetostatic energy with decreasing temperature. If wall energy drops less rapidly with increasing temperature than does the magnetostatic term, then the opposite scenarios apply. This predicted behavior relies on the assumptions that the particle is able to maintain a global energy minimum (GEM) domain state at all temperatures and that the total magnetostatic energy of the walls themselves can be ignored.

Using Amar’s (1958) model, Moskowitz and Halgedahl (1987) calculated the number of domains between room temperature and the Curie point in parallel-epipeds of TM60. As discussed earlier, they investigated two cases: dominant crystalline anisotropy (zero stress) and high stress ($\sigma = 100$ MPa). In TM60 grains larger than a few micrometers, most of their results gave an increase in the number of domains with heating. Exceptions to this overall pattern were cases in which walls broadened so dramatically with increasing temperature that they nearly filled the particle and rendered nucleation unfavorable. During cooling from the Curie point in zero field, the domain “blocking temperature” – the temperature below which the number of domains remained constant – increased both with decreasing grain size and with internal stress.

Micromagnetic Models

In contrast to classical models of magnetic domain structure, micromagnetic models do not assume the presence of discrete domains. Instead, they allow the orientations of M_s -vectors to vary among extremely small subvolumes, into which a grain is divided. A stable configuration is obtained numerically when the grand sum of exchange, anisotropy, and magnetostatic energies over all subvolumes is minimum.

Magnetic Domains, Fig. 5 Diagram illustrating the relative energies and energy barriers associated with local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by nucleation and denucleation energy barriers. In this diagram, the global energy minimum, or GEM, domain state has five domains

In rock magnetism, micromagnetic models have focused on magnetite, and they assume unstressed, defect-free crystals.

Moon and Merrill (1984, 1985) were the first in rock magnetism to construct one-dimensional (1D) micromagnetic models for defect-free magnetite cubes. Not only did they calculate the energies resulting from different numbers of domains within a grain of given size, but they also calculated the energy barriers associated with nucleation and denucleation of domains and domain walls. Their major breakthrough was the discovery that a particle can occupy a range of local energy minimum (LEM) domain states. Each LEM state is characterized by a unique number of domains and is separated from adjacent states by energy barriers. As illustrated in Fig. 5, the GEM state is the configuration of lowest energy but, owing to the energy barriers between states, a LEM state can be quite stable as well.

Several authors have extended micromagnetic calculations for magnetite to two dimensions (2D) and three dimensions (3D) (e.g., Williams and Dunlop 1989, 1990, 1995; Newell et al. 1993; Xu et al. 1994; Fabian et al. 1996; Fukuma and Dunlop 1998; Williams and Wright 1998). These models yield a variety of exotic, nonuniform configurations of magnetization, such as “flower” and “vortex” states. Analogous to Moon and Merrill’s results, these models produce both LEM and GEM states, although with very different spin structures from those of 1D models. For example, Fig. 6 illustrates a “flower” state in a cube magnetized parallel to the z -axis. The flower state is reminiscent of a classical SD state of uniform magnetization, except that the M_s -vectors are canted at and near the crystal surface. In relatively large cubes of magnetite – for example, 4 or 5 μm – both 2D and 3D models yield configurations closely

Magnetic Domains, Fig. 6 Illustration of a “flower” state obtained through three-dimensional micromagnetic modeling of a cube largely magnetized along the cube’s z -axis

approaching those of classical domain structures expected for magnetite, such as “body” domains and closure domains at the surface (e.g., Xu et al. 1994; Williams and Wright 1998). In submicron magnetite undergoing hysteresis, magnetization reversal can occur through LEM–LEM transitions (e.g., flower to vortex state) (e.g., Williams and Dunlop 1995).

Dunlop et al. (1994) used 1D micromagnetic models to investigate LEM states in stress-free magnetite particles during TRM acquisition. Their study was motivated by experimental results reported earlier by Halgedahl (1991) (see discussions below). Dunlop et al. (1994) calculated the energy barriers for all combinations among SD/two-domain/three-domain transitions during cooling from the Curie point of magnetite in a weak external field. According to their results, after acquiring TRM under conditions of thermal equilibrium, populations would be overwhelmingly biased toward GEM domain states, and an individual particle should not exhibit a range of LEM states after several identical TRM runs.

Using renormalization group theory, Ye and Merrill (1995) arrived at a different conclusion. According to their calculations, short-range ordering of spins just below the Curie point could give rise to a variety of LEM states in the same particle after replicate coolings.

Experimental Studies of Magnetic Domains

Methods of Imaging Domains and Domain Walls

Rock magnetists have mainly used three methods to image domains and domain walls: the Bitter pattern method,

which uses liquid magnetic colloid to image walls, with a resolution limit of about 1 mm (e.g., see details in Halgedahl and Fuller 1983); the magneto-optical Kerr effect (MOKE), which images entire domains from the rotation of the polarization plane of light reflected by a magnetized specimen (e.g., Hoffmann et al. 1987; Worm et al. 1991; Heider and Hoffmann 1992; Ambatiello et al. 1999); and magnetic force microscopy (MFM), which can image magnetic features as small as 0.01 mm through the voltage induced in a vibrating magnetic needle situated very close to a particle's surface (Williams et al. 1992; Proksch et al. 1994; Moloni et al. 1996; Pokhil and Moskowitz 1996, 1997; Frandson et al. 2004). Two other methods – transmission electron microscopy (TEM) and off-axis electron holography – have been used in some studies of magnetite, most notably magnetotactic bacteria and magnetite intergrowths in ulvospinel (Dunin-Borowsky et al. 2001; McCartney et al. 2001; Harrison et al. 2002).

Styles of Domains Observed in Magnetic Minerals of Paleomagnetic Significance

In rock magnetism, the majority of domain observation studies have focused on four magnetic minerals, all important to paleomagnetism: pyrrhotite (Fe_7S_8), titanomagnetite of roughly intermediate composition (near $\text{Fe}_{2.4}\text{Ti}_6\text{O}_4$, or TM60), magnetite (Fe_3O_4), and hematite (Fe_2O_3).

Owing to its high magnetocrystalline anisotropy constant and relative insensitivity to stress, pyrrhotite behaves magnetically as a uniaxial material. When studied with the Bitter colloid method, pyrrhotite often exhibits fairly simple domain patterns which suggest lamellar domains separated by 180° walls (Fig. 7a) (Soffel 1977b; Halgedahl and Fuller 1983).

Despite being cubic, intermediate titanomagnetites rarely, if ever, exhibit the arrays of closure domains, 71° , and 109° walls predicted from theories. Instead, these minerals often display very complex patterns of densely spaced, curved walls (Appel and Soffel 1984, 1985). However, some grains do exhibit a simple array of parallel walls, such as that shown in Fig. 8a (e.g., Halgedahl and Fuller 1980, 1981), but it is not unusual to observe wavy walls alternating with rows of reverse spikes (Halgedahl 1987; Moskowitz et al. 1988). Both simple and wavy patterns suggest a dominant, internal stress that yields a uniaxial anisotropy, although the origin of this stress is still unclear.

Small magnetite grains grown in a synthetic rocklike matrix with the glass-ceramic method (Worm and Markert 1987) generally display simple arrays of straight walls (e.g., Worm et al. 1991; Geiß et al. 1996) (Fig. 8b). In such samples, there appears to be a paucity of closure domains, perhaps the result of high internal stress generated by quenching during synthesis.

In contrast, domain images obtained from large crystals of natural magnetite and small magnetite grains in a variety of rocks reveal 180° , 71° , and 109° walls and closure domains, in accordance with theory (Bogdanov and Vlasov 1965, 1966; Smith 1980; Boyd et al. 1984; Ozdemir and Dunlop 1993, 1997, 2006; Ozdemir et al. 1995; Ambatiello et al. 1999). Evidently, internal stress is low in these natural magnetites, so that magnetocrystalline anisotropy is dominant.

To date, domain studies on hematite have been limited to large (e.g., 100 μm to 1 mm) platelets. Even large crystals such as these contain very few walls and a fairly simple domain structure, owing to hematite's weak spontaneous

Magnetic Domains, Fig. 7 Bitter patterns on a particle of natural pyrrhotite (a) after demagnetization in an alternating field of 1000 Oe and (b) in an apparently SD-like state after acquiring saturation remanence in 15 kOe

Magnetic Domains, Fig. 8 (a) Bitter pattern on a grain of intermediate titanomagnetite ($x \approx 0.6$) in oceanic basalt drilled near the Mid-Atlantic Ridge. (b) Bitter pattern on a grain of magnetite synthesized with the glass-ceramic method. In this particular state of magnetization, the grain contains four walls, whose lengths are commensurate with the particle's length. Note that one wall is pinned very near the particle's extreme left-hand edge. The small triangular patterns at the lower edge of the particle

represent walls which enclose small reverse spike domains. (c) Bitter pattern of a wall on a very large (approximately 150 μm width, 1 mm length) platelet of natural hematite from Elba, Italy. At most this platelet exhibits only 1–2 principal walls, although small edge domains are often observed. Apparently, the wall is bowing around a defect near the upper right-hand edge of the photograph. Only a small part of the crystal surface is shown

magnetization (about 2 emu/cm^3) and low magnetostatic energy (Fig. 8c) (Halgedahl 1995, 1998).

Number of Domains Versus Grain Size

Both Kittel's original model of domains in a semi-infinite platelet and calculations for finite grains by (e.g., Moskowitz and Halgedahl 1987) lead to the prediction that domain width $D \propto L^{1/2}$, where L is plate or particle thickness. These predictions are supported by domain studies of natural magnetic minerals which generally yield a power-law dependence of D on L , although the power may differ somewhat from 0.5.

Soffel (1971) was the first to study the grain-size dependence of the number of domains in a paleomagnetically important magnetic mineral. From Bitter patterns on grains of natural, intermediate ($x \approx 0.55$) titanomagnetite in a basalt, he determined that, on average, both D and N (number of domains = L/D) $\propto L^{1/2}$, where L was average particle size. His results yielded a single domain/two domain

transition size of 0.6 μm and a wall energy density of about 1 erg/cm^2 for this composition.

Similarly, from Bitter patterns on natural pyrrhotite in a Bavarian diabase, both Soffel (1977b) and Halgedahl and Fuller (1983) found that $D \propto L^{0.40}$ to $D \propto L^{0.45}$, depending on the magnetization state. For this pyrrhotite sample, the SD boundary fell between 1.5 and 2 μm . Geiß et al. (1996) obtained $D \propto L^{0.45}$ from Bitter patterns on synthetic magnetite particles grown in a glass-ceramic matrix (Worm and Markert 1987). They obtained a SD/two-domain transition size for magnetite of approximately 0.25 μm .

Domain Wall Widths

When studied in the scanning electron microscope (SEM), patterns of dried magnetic colloid afford high-resolution views of domain walls. Moskowitz et al. (1988) applied this method to polycrystalline pellets of synthetic titanomagnetite substituted with aluminum and magnesium

($\text{Fe}_{2.2}\text{Al}_{0.1}\text{Mg}_{0.1}\text{Ti}_{0.6}\text{O}_4$: “AMTM60”). Dried Bitter patterns on unpolished surfaces were virtually identical in style to those common to materials controlled by strong uniaxial anisotropy. Patterns indicated closely spaced stripe domains, sinusoidally wavy walls, and nested arrays of reverse spikes. Measurements from SEM images yielded wall widths between 0.170 and 0.400 μm .

Very high resolution images of domains and domain walls in magnetite have been obtained with MFM. The first images were reported by Williams et al. (1992), who recorded a magnetic profile across a 180° wall on a $\{110\}$ surface of a large natural magnetite crystal. Spins within the wall reversed their polarity of rotation along the length of the wall, demonstrating that walls in real materials can be much more complex than those portrayed by simple models. Using MFM, Pokhil and Moskowitz (1996, 1997) made a similar finding in glass-ceramic magnetite. Segments of opposite polarity were separated by Bloch lines, the transition regions where polarity changes sense. The number of Bloch lines within a wall varied among repeated alternating field (AF) demagnetization treatments. Thus walls, like particles, can occupy LEM states.

Owing to its high-resolution capabilities, the MFM can provide estimates of wall width. Proksch et al. (1994) obtained MFM profiles across a 180° wall on a $\{110\}$ surface of natural magnetite, thus obtaining a wall width of about 0.21 μm .

Experimental Evidence for Local Energy Minimum (LEM) Domain States

In their study of Bitter patterns on natural pyrrhotite, Halgedahl and Fuller (1983) noted that grains of virtually identical size could contain very different numbers of domains, despite these same particles having undergone the same magnetic treatments. Moreover, they found that an individual particle could arrive in very different domain states – that is, with different numbers of walls – after different cycles of minor hysteresis.

These observations led Halgedahl and Fuller (1983) to the conclusion that a particle could occupy domain states other than the ground state. Subsequent domain observation studies by Halgedahl on AMTM60 and by Geiß et al. (1996) on magnetite provided strong evidence for LEM states in other magnetic minerals.

LEM States and Thermomagnetic Treatments

A particularly unexpected type of LEM state in pyrrhotite and intermediate titanomagnetite is a SD-like state that certain particles can occupy after being saturated in a strong external field, even though these same particles readily accommodate walls in other states of magnetization. Bitter patterns on intermediate ($x \approx 0.6$) titanomagnetite in oceanic basalt and on natural pyrrhotite in diabase were studied during

hysteresis by Halgedahl and Fuller (1980, 1983). In states of saturation remanence, most particles in a large population contained one or more walls, as expected on the basis of previous theories (Fig. 7a). However, several tens of percent of the finer (5–15 μm) particles appeared saturated after the maximum field was shut off (Fig. 7b). Halgedahl and Fuller (1980, 1983) proposed that grains that failed to nucleate walls could make a substantial contribution to saturation remanence. Particles in SD-like states remained saturated, until nucleation was accomplished by applying a back field of sufficient magnitude, and this nucleation field dropped off with increasing grain size L according to a power law in $L^{-1/2}$. Similarly, Boyd et al. (1984) reported Bitter patterns on natural magnetite grains carrying saturation remanence, and these patterns suggested SD-like states. These results were surprising, in view of magnetite’s strong tendency to self-demagnetize.

Subsequent domain observations and hysteresis measurements of hematite platelets from Elba, Italy demonstrated that, after exposure to strong fields, even large crystals could arrive in states of near-saturation. Back fields were necessary to nucleate principal domains, and, similar to pyrrhotite, these nucleation fields also followed a power law in $L^{-1/2}$ (Halgedahl 1995, 1998).

Results from titanomagnetite and pyrrhotite suggesting SD-like states were interpreted by Halgedahl and Fuller (1980, 1983) in light of previous theoretical and experimental work on high-anisotropy, industrial magnets. In such materials, nucleation of walls is an energetically difficult process, because the internal demagnetizing field, which triggers nucleation, may be too weak to overcome the anisotropy field, which hinders nucleation (Brown 1963; Becker 1969, 1971a, b, 1976). Such particles may require an external back field, which aids the demagnetizing field in order to nucleate walls and accompanying domains.

The style of domain structure and the range of LEM states that a particle can occupy can depend on thermomagnetic history. From Bitter patterns on natural, polycrystalline pyrrhotite, Halgedahl and Fuller (1981) discovered that crystallites displayed arrays of undulating walls on their surfaces after acquiring TRM in a weak external field. By contrast, after AF demagnetization in a strong peak field the same crystallites exhibited planar walls. Evidently, cooling locked in a high-temperature configuration of walls whose curved shapes promoted lower magnetostatic energy than would a planar geometry.

As indicated by Moon and Merrill’s theoretical results for magnetite, a particular LEM state can be stable across a broad range of grain size. This prediction is born out by experiments by Halgedahl and Ye (2000), who investigated the effects of mechanical thinning on domain states in natural pyrrhotite. Individual pyrrhotite grains in a diabase were mechanically thinned and their Bitter patterns observed after

Magnetic Domains,

Fig. 9 Bitter patterns on a grain of natural pyrrhotite in a diabase before and after mechanical thinning. (a) Initial state, before thinning. (b) After thinning the particle to about one-half of its original length along a direction parallel to the trends of the Bitter lines. (c) Final state, after the particle has been thinned to about one-fourth of its original length

each thinning step. Despite some grains being thinned to about one-fourth of their initial diameter, the widths of surviving domains and positions of surviving walls remained unaffected (Fig. 9). Neither nucleations nor denucleations were observed, although calculations indicated that thinning would cause significant changes in GEM domain states.

Bitter patterns on crystallites of polycrystalline AMTM60 were studied after many replicate TRM acquisition and AF demagnetization experiments (Halgedahl 1991). In each particle, the number of domains varied from one experiment to the next, defining a distribution of LEM states. For states of weak-field TRM, this distribution could be broad and could include single-domain-like states (Fig. 10). After replicate AF demagnetizations, however, typical distributions were narrow and clustered about a most probable state, possibly the GEM state.

Evolution of Magnetic Domain Structures at Elevated Temperatures

The manner in which domain structure evolves with temperature carries clear implications for TRM. Cooling-induced nucleations and denucleations of walls/domains could trigger sudden changes of the internal demagnetizing field. As a result, preexisting walls which survive a domain transition could be dislodged from imperfections where they were pinned initially at higher temperatures.

The first Bitter patterns observed on magnetite above room temperature in the Earth's field were made by Heider et al. (1988), using hydrothermally recrystallized crystals. Depending on the particle, Bitter patterns could be followed to approximately 200 °C, above which temperature the

patterns grew too faint to discern. Surprisingly, heating to very moderate temperatures drove certain walls across much of a particle; in some cases, denucleation occurred. Upon cooling, walls reassembled in a similar, though not identical, arrangement to that observed initially at room temperature. In some cases, repeated thermal cycling between room temperature and about 200 °C produced different numbers of domains in the same particle.

Ambatiello et al. (1999) used the MOKE to study domain widths versus temperature in several large (several mm) crystals of natural magnetite. At room temperature, {110} planes were dominated by broad lamellar domains that terminated in closure domains at crystal edges. On {111} planes, they found complex, nested arrays of very small closure domains, which finely subdivided the main closure structure. Domain widths generally increased with heating, and such changes were thermally reversible. To explain their results, these authors hypothesized that heating promoted an increasingly finer subdivision into small domains near the crystal surface; this would reduce magnetostatic energy with heating and thus cause broadening of body domains (also see Muxworthy and Williams 2006).

Bitter patterns observed at elevated temperatures on natural, intermediate titanomagnetites were reported by Soffel (1977a), Metcalf and Fuller (1987a, b, 1988), and Halgedahl (1987). During heating, patterns gradually faded to obscurity, with few significant changes in domain structure. Remarkably, some titanomagnetite particles studied by Metcalf and Fuller (1987a, b, 1988) displayed no Bitter lines after cooling from the Curie point in the Earth's field. This observation provided evidence for Halgedahl

Magnetic Domains,

Fig. 10 Bitter patterns on a crystallite of titanomagnetite (“AMTM60”: see text) after each of eight replicate TRM acquisition runs in the Earth’s field

and Fuller’s (1983) earlier proposal that weak-field TRM acquired by populations of PSD grains could, in part, be attributable to particles which failed to nucleate walls during cooling.

The possible importance of LEM states to TRM acquisition was raised by work on synthetic, polycrystalline AMTM60 with a Curie point near 75 °C (Halgedahl 1991). As shown in Fig. 10, replicate TRM experiments often produced different numbers of domains in the same particle. Some of these states suggested that the particle was entirely saturated, with no visible Bitter lines, or nearly saturated, with only small spike domains at grain boundaries. Patterns that evolved during cooling revealed that denucleation was one mechanism by which a particle arrived in a final LEM state. Denucleation occurred either

through contraction of large, preexisting spike domains, or by straight walls moving together and coalescing into spikes. Often, spikes would collapse altogether. In some cases, denucleation left behind large volumes which, apparently, contained no walls, although walls were present elsewhere in the grain. In other cases, denucleation left behind a grain that appeared nearly saturated, but for small edge domains. These results led to the idea of trans-domain TRM (Halgedahl 1991).

Magnetic Domain Structure in Magnetite at Low Temperatures

Magnetite undergoes two types of transitions at low temperatures, which can profoundly affect domain structure and remanence (e.g., see detailed discussions in Stacey and

Banerjee (1974), Dunlop and Ozdemir (1997)). At the isotropic point (approximately 130 K), the first magnetocrystalline anisotropy constant, K_1 , passes through zero as it changes sign from negative at temperatures above the transition to positive below it. At the Verwey transition, T_v (approximately 120 K), magnetite undergoes a crystallographic transition from cubic to monoclinic.

Thus at 130 K domain walls should broaden dramatically, because wall width is proportional to $K_1^{-1/2}$. It follows that, by passage through 130 K, walls may break free of narrow defects which pinned them at other temperatures. At the Verwey transition, the easy axis of magnetization changes direction. In multidomain and pseudosingle-domain magnetite, these thermal passages may cause demagnetization and complete reorganization of domain structure. Low-temperature demagnetization has proved useful in removing certain spurious components of NRM which are surprisingly resistant to thermal demagnetization above room temperature. Thus it is important to determine how these transitions affect domains.

Using an MFM specially adapted to operate at low temperature, Moloni et al. (1996) were the first to image domains on {110} magnetite planes at temperatures near the two transitions. As the crystal was warmed from 77 K to a few degrees just below T_v , the domain structure disappeared entirely below the instrument's noise level, evidently undergoing a complete reorganization near the crystallographic transition.

Magnetic Gradiometry

Harald von der Osten-Woldenburg
National Heritage Department, Regional Government of
Baden-Wuerttemberg, Esslingen am Neckar, Germany

Definition

Magnetometer	Instrument with a single sensor that measures magnetic flux density.
Magnetic gradiometer	Pairs of magnetometers with sensors separated by a fixed distance.

The Earth's magnetic field at any point on or near the Earth's surface is the vector sum of the contributions from the primary field due to the dynamo in the Earth's liquid core and the crustal field from the magnetic mineral content of local rocks. This vector has both an orientation and an amplitude. Slight changes in any direction influence the orientation and amplitude. Introduce a highly magnetic rock formation into an otherwise homogenous host, and the local magnetic vector will change. In a three-dimensional world, there are nine (3×3) spatial gradients forming a tensor which defines the anomalous field.

On the Conceptual Design of Gradiometers

A gradiometer is a special measuring instrument that consists of more than one (usually two, rarely three or four) magnetometers. The differences between the readings of the sensors are seen as an approximation to the gradient of the magnetic field along their alignment. The (usually) two magnetometers of a gradiometer are arranged either vertically or horizontally. The distance of the two sensors can vary between several decimeters (for archaeological or environmental mapping) and several kilometers (for research of the deeper-lying geological structures of the Earth's crust, see ► [“Magnetic Methods, Airborne”](#)) depending on the field of application.

Magnetometers

Quantum magnetometers (see also ► [“Magnetometers”](#)) and saturable-core magnetometers are generally suitable for use in gradiometers. Alongside the fluxgate saturable-core magnetometers, cesium vapor magnetometers have become a standard in many areas (aeromagnetic survey, marine geophysics, environmental geophysics, and archaeological prospection) due to the improved noise signal levels against the

Overhauser magnetometers or the helium-cooled sensors (Nabighan and Asten 2002).

Thanks to new technological advances, for example, in the further development of magnetic gradiometer systems based on the superconducting gradiometric sensors SQUID (superconducting quantum interference device), systems are now available that enable very precise measurements of extremely small magnetic field changes. Due to this development, the importance of magnetic gradient tensor and field vector measurements has increased significantly in many applications (Clark 2012). Thus, a significantly higher magnetic and spatial resolution of magnetic maps is achieved than with conventional magnetometers.

Fluxgate gradiometers measure a single component of the Earth's magnetic field (usually the vertical component), while gradiometers consisting of quantum magnetometers (i.e., proton precession and cesium vapor sensors) measure the component of an anomaly in the direction of the Earth's ambient magnetic field, as this is much larger than the anomaly itself (Blakely 1996). Additionally, fluxgate magnetometers are directionally sensitive and subject to a temperature-related drift, and therefore often have to be recalibrated during measurements.

Instead of using a pair of different magnetic field sensors and differentiating their outputs in order to derive a magnetic gradient value, a single sensitive element can be used for measuring directly a magnetic gradient. This is done by the use of a stiff metallic string clamped at both ends and pumped with an AC current, the frequency of which is tuned to the second eigenmode of the string. The string is excited at that eigenmode in the presence of a quasi-static magnetic gradient. Then, the corresponding mechanical displacements of the string can be measured by the use of an inductive technique with an instrumental noise envelope of less than $\pm 10^{-12}$ m, per 1 s measurement interval (Veryaskin 2001). Sheng et al. (2017) describe a new magnetic gradiometer based on optical spectroscopy of alkali atoms in the vapor phase. This type of magnetic gradiometer can be extremely interesting for applications in archeology and environmental sciences.

In the field of environmental geophysics, there has been a trend towards the use of multi-channel gradiometer systems in recent years (Fig. 1). On a trailer, usually 10 or up to 20 probes are pulled over the measuring surface at a distance of 0.50 m (or 0.25 m if 20 probes are used) by an off-road vehicle. The georeferencing is done in real time by means of a differential GPS system.

Advantages and Limitations

In measurements with a gradiometer, the measured signal amplitude of the magnetic anomaly of an interfering body decreases by the power of three or four depending on the distance between the two sensors. A gradiometer is therefore

Magnetic Gradiometry, Fig. 1 The 10-channel fluxgate gradiometer system, manufactured by Eastern Atlas GmbH, Berlin, using the Fluxgate sensors of the Institute Dr. Foerster, Reutlingen, Germany. Magnetic field data are georeferenced in real time using a differential GPS system

somewhat less sensitive to deeper-lying features than a total-field magnetometer, where the signal amplitude of an anomaly decreases by the power of three depending on the distance of the sensor to the interfering body. However, gradiometers react very sensitively to interfering features close to the surface and possess a higher spatial resolution in small-scale structures than total-field magnetometers. The variability in time of the Earth's magnetic field and other sources of interference that are far enough away from the gradiometer, and whose influence on the sensors is equal or at least of a similar level during gradiometer measurements, can be eliminated – or at least significantly reduced – by subtracting the simultaneous readings of the two sensors from one another. An advantage of gradient measurements, arising from the ambiguity present in all potential field measurements, is the suppression of broad regional changes in the magnitude of the magnetic field – the long wavelength component. With gradiometer measurements, the local variations are enhanced, making small and weakly magnetic targets recognizable. Gradiometer surveys are particularly useful in areas that are geologically complex. Due to the resulting difference, the magnitude of the anomalies is, however, smaller than the amplitude that one would achieve with a total-field

magnetometer. This means that a total-field magnetometer can detect anomalies of smaller and deeper-lying features which cannot be detected by a gradiometer. Fluxgate gradiometers are very sensitive to their position in relation to the magnetic vector field: an ever so slight change in the inclination of the instrument during measurements can lead to incorrect results (Schmidt and Clark 2000).

The use of vertical gradiometers for magnetic mapping effectively removes the time variations in the magnetic field map without having to establish base stations, networks, or tie lines and is the only insurance against elimination of the high-frequency component that contains the small or weakly magnetic targets. Gradiometers have shown that they can offer a high degree of immunity from diurnal and minor magnetic storm activity in the ambient magnetic field; they can enhance near-surface, small, or weakly magnetic anomalies.

Areas of Application

Vertical axial gradiometers are used for measuring the vertical differences (the vertical gradient) in the vertical component of

Magnetic Gradiometry,

Fig. 2 The four-channel fluxgate gradiometer of the Institute Dr. Foerster, Reutlingen, Germany. Measurements in a grid of 0.05 by 0.06 m are possible with this device. The two fluxgate sensors are 0.65 m apart

the Earth's magnetic field. This configuration is commonly used for ground-based geophysical surveys in the field of environmental geophysics, in areas with complex geology and archaeological prospecting, as the influences of deeper-lying interferences can be suppressed by this setup of the sensors. For practical reasons, the distance between the sensors of a gradiometer used for ground-based surveys lies somewhere between 0.5 and 1 m. As a rule, the ground penetration and detection ranges to about one to two meters below the surface. Deeper detection can be achieved if the interfering body is accordingly large and strongly magnetized. Fluxgate gradiometers are commonly found in environmental geophysics and in archaeological prospecting (Fig. 2). Surveys can be conducted at faster rates, and the highest requirements for spatial resolution of the smallest archaeologically relevant features can be met with measurement grids of 0.05 by 0.06 m without the fluxgate sensors influencing each other. Sometimes, these very small measuring intervals are necessary in archaeological prospecting in order to achieve the best possible spatial resolution of archaeological features (von der Osten-Woldenburg et al. 2006). The magnetic gradiometer map of a Roman fort and its adjacent settlement (Fig. 3) that was obtained with a measurement grid of 0.25 by 0.25 m shows a large number of diverse, often very characteristic anomalies which allow conclusions to be drawn on the position, shape, and size of defensive trenches, centrally located staff buildings with stone foundations, wooden barracks with their hearths, as well as buildings (stone-foundation buildings, street layouts, cellars, and pits) of the settlement adjacent to the fort.

Magnetic gradiometry is also employed in forensic geophysics, even if the radar method has been established as the standard procedure (Cheetham 2005; Hansen and Pringle 2013). However, certain general conditions such as a sufficient distance to the iron cores of reinforced concrete, fences, and other metal constructions must be provided, and it must be ensured that there is no metal refuse in the ground itself. The procedure is identical to that of archaeological prospecting: research is undertaken in small-scale, near-surface survey as the burials themselves are usually close to the surface. The human body only has a small measure of magnetic susceptibility, so a direct detection of the remains by magnetic gradiometry is not possible. But the excavation of a grave and the disruption of strata leads to disturbances of the layers of soil close to the surface that are usually magnetically homogenous, and the refilling of the grave with the excavated material – in which the magnetic particles are now statistically aligned – usually generates weak geomagnetic anomalies, often smaller than 2–3 nT (Fig. 4). The displacement of soil with a significantly higher susceptibility by the human body can intensify this effect.

Axial gradiometers are also used in aeromagnetic surveys (see ► “Magnetic Methods, Airborne”), that is, by helicopter for the detection of ordnance remains close to the surface (Doll et al. 2006), in the prospection of mineral deposits (see ► “Magnetic Methods, Surface”) and for research of anomalies in the Earth's magnetic field and deeper-lying geological structures of the Earth's crust (see ► “Magnetovariation Studies”) from stratospheric balloons with a base length of sensors as far as 6 km apart (Webers et al. 2009).

Magnetic Gradiometry, Fig. 3 Archaeological survey: Magnetic gradiometer map of a neolithic (5000 BC) to the La-Tène-period (sixth/seventh century BC) sequence of settlements on the mountain Goldberg, part of the Nördlinger Ries, Germany. On the plateau of the mountain

floor plans of the houses are clearly visible. The defensive structures in the west of this settlement date back to 4500 BC. West-East extension of the magnetogram: about 650 m

Magnetic Gradiometry, Fig. 4 Forensic geophysics: Detection of a burial at the edge of a field (marked by a circle). The linear anomalies are produced by drainage pipes and geological structures in the substratum

Transverse and longitudinal gradient magnetic measurements are applied in aeromagnetic surveys (Hogg 2004), in marine geophysics, and space exploration (see ► “[Magnetic Methods, Principles](#)”). The distance of the magnetometers from one to the other can range from 1.5 m (e.g., in cable and pipeline survey, or for detecting smaller metallic objects) to more than 500 m (for the detection of magnetic sediments close to the surface, shipwrecks, and the prospecting of mineral deposits), depending on the required area of application.

Magnetic gradient tensor data are used, for example, for a better determination of the small-scale structure of the Earth’s lithospheric field (Kotsiaros and Olsen 2012). They can also be used to clean up areas which are contaminated with various types of unexploded ordonances (UXO) and landmines (Zuo et al. 2017).

Summary

Magnetics belong to the most commonly used methods for prospecting in applied geophysics when attempting to infer the position, geometry, and physical parameters of a body of interference or geological structure through the measurement of magnetic anomalies (Schmidt and Clark 2006).

Gradiometers with two vertically arranged magnetometers that are positioned between 0.5 and 1 m apart, and which measure the vertical gradient and vertical component of the Earth's magnetic field, have distinct advantages over total-field magnetometers, especially in ground-based magnetic measurements in environmental geophysics (surveying of contaminated sites, examination of building construction sites, archaeological research of former settlements): they offer a high resolution in smaller features which is, however, gained at the cost of a lesser penetration of the ground in comparison to measurements made with total-field magnetometers. Additionally, they are very sensitive to close-by sources of interference. Background interference (such as the variability in time of the Earth's magnetic field and other nearby sources of interference) can be eliminated or significantly reduced by subtracting the simultaneous readings of the two sensors in the gradiometer arrangement.

Magnetic Gradiometry in Archaeo-geophysics

Harald von der Osten-Woldenburg

National Heritage Department, Regional Government of Baden-Wuerttemberg, Esslingen am Neckar, Germany

Definition

Geophysical measurement procedures have become an important and integral part of surveying methods in archaeological disciplines. Unlike hard prospecting, where archaeological remains are analyzed during an excavation which ultimately leads to their destruction, geophysical measurement procedures are commonly referred to as soft prospecting. They are nondestructive and leave the ground undisturbed. Geophysical methods are therefore often used in the targeted preparation of rescue or research excavations (von der Osten-Woldenburg 2005). They can save time and money by helping to define the location and size, apparent state of preservation, and probable age of the surveyed archaeological remains. These measurement procedures are also widely used when documenting the sites of archaeological settlements: sites that can be preserved for coming generations as they remain undisturbed in the ground.

Magnetic gradiometry is one of the most important methods when it comes to choosing from the range of geophysical measurement procedures that are suitable for archaeological surveys, and it is normally used as the initial prospecting technique. The reasons for this can be found in the usually very conclusive results, quick mapping of the site with a high level of data density, simple usage of the respective measuring instruments, and the relatively low

requirements for data processing. The reasons for the existence of magnetic and therefore archaeologically relevant anomalies may include: buried artefacts containing ferromagnetic metals; long-term changes in magnetic properties as a result of the effects of fire, for example in the case of fires; changes in the distribution of magnetic properties in the ground due to the excavation of pits or defence trenches (Ernenwein and Hargrave 2009).

Indications on the presence of yet undiscovered buried settlement sites can be provided by scanning the earth's magnetic field in close proximity to the ground and recording the weakly defined, archaeologically caused geomagnetic anomalies. This geomagnetic mapping is an important tool for the discovery of archaeological settlement traces in unmapped terrain where there are no stray material finds, no indications in historical sources and no aerial photography findings. Additional methods that complement geomagnetic gradiometry – such as electrical resistivity tomography or ground penetrating radar – must be employed where necessary to verify the subareas in which the contrast of the magnetic susceptibilities, or the residual magnetization between the archaeological objects and the soil in which they are embedded, is faint and therefore appears in the magnetogram only as areas of weakly defined anomalies.

Advantages of Magnetic Gradiometers

Gradiometers used in archaeological prospecting normally consist of an array of two sensors that are aligned at a vertical separation of 0.5 m, more commonly 0.65 m, and in some instances just over 1 m. They can detect magnetic anomalies that are weak, just beneath the surface, or of a limited size – all typical circumstances for archaeological objects – with more clarity than conventional measurements that are taken of the total intensity of the earth's magnetic field in ground proximity while using only a single sensor. They also have a much greater spatial resolution than the single-sensor, total-field measuring magnetometer (GEMSystems 2019). For that reason alone, the gradiometer is the ideal instrument for detecting smaller anomalies that lie closer to the surface and extremely practical when it comes to archaeological mapping.

It has also been shown that gradiometers have a high degree of insusceptibility toward the daily smaller magnetic storm activities that occur in the earth's magnetic field (GEMSystems 2019). Measurements with an additional base station magnetometer that eliminates the variations in the earth's magnetic field from the recorded data are therefore unnecessary.

How deep down a gradiometer can detect archaeological structures depends on the one hand on the vertical separation between the two sensors, and on the other on the intensity of the contrast of the magnetic susceptibility, or the residual

magnetization between the archaeological object and the soil in which it lies. Usually depths of 1–2 m can be reached under ideal conditions.

Instruments

Magnetic gradiometry is carried out by using magnetometers that possess extremely high susceptibility and stability. A number of magnetometer sensors and configurations are available. Cesium vapor sensors or fluxgate sensors, used in pairs in a gradiometer configuration, are a common choice. In practice there are almost no differences in the capacity between the two types of sensor when they are used in a gradiometer configuration, apart from a higher sensitivity of cesium vapor sensors over the fluxgate variant. Cost and weight factors are the main reasons that fluxgate gradiometers are the preferred choice in archaeological field surveys.

Standard gradiometers measure the vertical gradient of the earth's magnetic field locally and in close proximity to the ground. This can be overlaid by faintly magnetic subsurface archaeological structures from former settlement sites. Composite maps, so-called magnetograms, which contain the magnetic image of subsurface archaeological structures, are then created from the measured variations of this magnetic gradient.

As a rule, fluxgate gradiometry is carried out using a portable single or double gradiometer, or with up to four gradiometers that are mounted to a nonmetallic cart or carrying structure (Fig. 1). More recently, a growing number of vehicle-based measuring configurations have been used (Linford et al. 2015; Schneidhofer et al. 2016) that can carry up to 10 (Fig. 2) or even 20 fluxgate gradiometers (Eastern Atlas 2019; SENSYS Sensorik, & Systemtechnology 2019). These sensor carts are towed behind an off-road vehicle or an ATV and record the earth's magnetic field in close proximity to the ground along a profile that can be up to five meters wide while the separation between the gradiometers can range from 0.25 m to 0.5 m.

Procedure in the Field

Maps resulting from surveys that are made with an adequately high spatial resolution can provide quite recognizable and detailed contours of the buried structures. This allows a clear archaeological interpretation to be made. The necessary spatial resolution is, of course, dependent on the size of the structures that are under investigation. But as the actual size is usually not something that is known before the survey, the highest possible resolution must be chosen from the outset. Experience has shown that measurements that are taken with a maximum separation of 0.25 m along the profile line and at

Magnetic Gradiometry in Archaeo-geophysics, Fig. 1 Using a four-channel fluxgate gradiometer (FEREX 4.032 by Institut Dr Foerster, Germany) on the site of the Lauchheim Roman fort (Fig. 5). (Photo Credit: Harald von der Osten-Woldenburg)

Magnetic Gradiometry in Archaeo-geophysics, Fig. 2 A geomagnetic survey of up to 25 ha per day can be achieved – subject to soil conditions – with a ten-channel fluxgate gradiometer array (LEA D2 by Eastern Atlas, Germany) and a differential GPS system. (Photo Credit: Harald von der Osten-Woldenburg)

an interval of 0.25 m are absolutely necessary to create and improve the composite image and therefore to address and interpret smaller magnetic anomalies.

Surveys with gradiometer arrays, such as the single channel (viz. an instrument consisting of one gradiometer) FM36 or FM256 (both with a vertical sensor separation of 0.5 m) by Geoscan Research, Bradford/UK (Geoscan Research 2019), the two-channel Grad601 (vertical sensor separation: 1 m) by Bartington, Witney/UK (Bartington 2019), the FM256 Dual Gradiometer System by Geoscan Research (horizontal separation between the two gradiometers: 1 m), or the four-channel FEREX 4.034 by Institut Dr Foerster, Reutlingen/Germany (Foerster 2019), are usually performed within a regular grid and without the use of a GPS receiver attached to the gradiometer. In order to accomplish this, several grids must first be pegged with sizes that can range – depending on the instrument that will be used – from 20 m × 20 m to 40 m × 40 m. Guidelines are strung within these grids that

are one or two meters apart and allow the precise following of the parallel-aligned profiles. Gradiometers equipped with an audio signal (metronome) in combination with respective markings along the lines make it easier to follow a predefined speed when taking the measurements, which makes the magnetic recording of the buried structures as distortion-free as possible.

Grids are not necessary in cases where a multichannel measurement system with at least ten fluxgate gradiometers is towed behind an off-road vehicle or ATV. Moreover, these surveys can also be seamlessly performed in irregularly shaped areas. This is made possible by using an RTK-DGPS system: The base station of a differential GPS system is set up at the edge of the survey area. The GPS-rover station is firmly attached to the measurement cart (Fig. 2). Such an array enables – depending on the soil conditions (e.g., meadow and ploughed field) – the mapping of relatively large areas of up to 25 ha per day with a high measurement density. In

additional geophysical surveying methods (e.g., ground penetrating radar). (Photo Credit: Harald von der Osten-Woldenburg)

addition, there is also the advantage that the georeferencing of the measurements, which takes place at the same time as the gradiometer survey, allows for on-site processing of the data within minutes and the creation of the magnetogram. This provides important information already during the measurement process that can help to decide if the survey area needs to be extended or not.

Case Studies

Magnetic gradiometry is virtually predestined for the discovery of former settlement sites in until then archaeologically unidentified locations. The availability of multichannel gradiometers has enabled the geomagnetic surveys of larger suspected sites to be completed within a couple of hours.

In the case of Emerfeld (in the district of Biberach, Germany), there were no indications whatsoever from either stray material finds, historical sources, or aerial archaeology. Measurements that were taken in a single day resulted in at least three locations being recorded that indicate toward the presence of a prehistoric settlement. They are marked in Fig. 3 by a circle and two ellipses. These are the characteristic geomagnetic anomalies associated with pit houses. The magnetogram also contains information on traces of ploughing (fine, parallel aligned lines), geological structures such as erosion gullies, and modern disturbances such as the location of utility poles for the power lines (marked as bright anomalies in squares) as well as a disused power line (the dark anomalies in squares).

There are situations in which gradiometers may only provide an indication that archeologically relevant structures might be present. A more detailed documentation through the targeted use of other methods becomes necessary in

cases where the initial discovery and localization is made in this manner. One such example is the discovery of a building from the Roman period (Fig. 4, left) that was recorded in just 2 min during the course of a geomagnetic gradiometry survey with a vehicle-based ten-channel fluxgate gradiometer. In a subsequent ground penetrating radar survey (SIR-4000 by GSSI, USA, 400 MHz antenna, 0.5 m profile interval), the floor plan became much clearer (Fig. 4, right). The expenditure of time for this latter survey, excluding the pegging of the grid, was higher by a factor of 10. Conversely, the initial use of the ground penetrating radar in this area would have been highly inefficient and the survey could have taken several days before the building would have been documented.

Do Different Measurement Instruments Deliver Different Results?

During road works, the existence of a small, until then unknown Roman fort, was recorded in a magnetic gradiometer survey (Fig. 5a). The survey was done in October 1992, using a British Geoscan Research FM36. Profile separation and measurement-point interval were both 0.25 m. The outer ditch, foundations of the watchtowers, the fort's main road, and post holes belonging to the fort's wooden buildings are clearly recognizable in the magnetogram, as well as a Roman estate to the east of the fort and a medieval gallows in the northern part of the fort. In July 2009, the fort, which is located in an area of meadows and therefore lies protected in the ground, was reexamined with magnetic gradiometry (Fig. 5b). This time a four-channel German fluxgate gradiometer system FEREX 4.032 by Institut Dr Foerster was used (Fig. 1). The system was equipped with CON650 sensors (vertical separation between sensors: 0.65 m). The interval

Germany. Right: LEA D2, Eastern Atlas, Germany. Multichannel gradiometers allow for larger areas to be surveyed in less time. The single-channel gradiometer FM36 provided more detailed information on this small fort. (Photo Credit: Harald von der Osten-Woldenburg)

between the measuring points was 0.05 m, the profile separation 0.25 m. The data was resampled based on a grid of $0.25 \text{ m} \times 0.25 \text{ m}$. The advantage of this instrument lies in the much higher prospecting speed over that of the FM36. This allowed a geomagnetic mapping of the entire meadows, and during the survey, a further Roman ditch system was discovered, the use of which is so far unknown (horse paddock?). A third survey of the site was undertaken in March 2015, using a ten-channel German Eastern Atlas LEA D2 system (Fig. 2). The sensors used in this survey were the same as those in the four-channel FEREX-system (CON650). The separation between the sensors was 0.5 m, and measurements were taken on average at an interval of 3 cm and a speed of 10 km/h. This data was also resampled based on a grid of $0.25 \text{ m} \times 0.25 \text{ m}$ (Fig. 5c).

Conclusion

Even if a comparison between the FM36 sensors and the Foerster-CON650 sensors is not strictly allowed – since the separation of the fluxgate sensors of the FM35 is 0.5 m, and that of the CON650 is 0.65 m – it still shows that the measurements taken by foot were slightly more exact and that they contain more detail than the multichannel instrument surveys. The vehicle-based ten-channel Foerster gradiometer measurements, for example, do not show the fort's eastern road, whereas they are clearly recognizable in the FM36 survey.

However, the benefits of vehicle-based surveys – covering larger areas in less time – probably outweigh the disadvantages. Only for the actual documentation of suspected

archaeological objects would it be advisable to resort to targeted resurveying by foot.

Aeromagnetics

Definition

Airborne magnetic surveys comprise measurements of the Earth's magnetic field made with a magnetometer mounted on an aircraft.

Introduction

Making measurements from the air of the Earth's magnetic field is a well-established geophysical survey method. The normal practice is to measure the scalar amplitude of the magnetic field in the survey area, this being referred to as the total magnetic intensity (TMI), the name reflecting the fact that the measurements represent the resultant of all the magnetic fields, of whatever source, in the vicinity of the measurement. The major contributions come from the geomagnetic field and the fields due to magnetic rocks in the upper crust, the latter being the fields of interest.

Initially used to infer the depth to magnetic rocks beneath nonmagnetic cover in sedimentary basin studies and for identification of major lineaments, the products from aeromagnetic surveys have evolved to now be a reliable means of creating detailed maps of the near-surface geology. Current developments in aeromagnetism are mostly related to the increasingly sophisticated inference of the 3D distribution of

magnetism in the Earth's crust using inverse modeling methods.

Comprehensive accounts of aeromagnetic data, acquisition, processing, and interpretation are provided by Gunn (1997), Reeves (2005), Isles and Rankin (2013), and Dentith and Mudge (2014).

Making Magnetic Measurements from the Air

Airborne magnetic data are acquired as a series of parallel “survey” or “flight” lines and more widely spaced orthogonal “tie” lines (Fig. 1). The purpose of the tie lines is to create repeat measurements at the locations where they cross the flight lines, which are required during processing of the data (see below).

An advantage of making magnetic measurements from the air is that unless the survey area is small, typically less than a few square kilometers, it is much faster and cheaper to acquire the data than for a ground-based survey. The main disadvantage is that turbulence and variations in topography, especially if the terrain is rugged, may seriously affect the ability to position the aircraft as would be preferred and also affect the individual measurements in a hard to predict way.

Equipment

Airborne measurements are routinely made using fixed-wing aircraft and helicopters. Surveys using fixed-wing aircraft are significantly cheaper than helicopter surveys, but helicopters have the advantage of being able to fly lower and better maintain a consistent ground clearance in rugged terrain, but have the disadvantage of being less stable survey platforms.

To reduce effects of magnetic fields originating in the aircraft the magnetic sensor, usually a cesium vapor magnetometer (see ► “Magnetometers”), is located as far as possible from the main body of the aircraft and hence the magnetic fields associated with ferrous components and electric currents. For fixed-wing aircraft the magnetic sensor is mounted in a “stinger” located aft of the aircraft. In helicopters the sensor may be in a “boom” that positions the magnetometer in front of the aircraft or it may be within a towed “bird.” The bird is a bomb-like device suspended on a cable beneath the aircraft. A “compensation” system within the aircraft is used to further reduce the effects of magnetic fields originating from the aircraft.

In addition to carrying one or more magnetometers, the survey aircraft also measures terrain clearance using an altimeter and GPS position and time. One or more “base station” magnetometers are also deployed on the ground to measure temporal changes in the magnetic field in the survey area to enable such variations to be removed from the data (see below).

Magnetic Methods, Airborne,**Fig. 1** Schematic illustration of the flying pattern used in aeromagnetic surveys**Magnetic Methods, Airborne, Fig. 2** Profile of total magnetic intensity across a dyke-like magnetic body. The four profiles correspond with the bodies at different depths in (c). The profiles in (b) represent

variations in TMI. In part (a) the amplitudes have been normalized to the profile with maximum amplitude (shallowest source)

The Importance of Source-Sensor Separation

An important source of noise in aeromagnetic data is associated with changes in distance between the magnetic sensor

and the magnetic materials. Any changes in this distance will create variations in TMI, which could easily be confused with those caused by changes in the local geology. As the distance

 (b) vertical terrain clearance.
 (Based on data in Flis and Cowan
 2000)

increases the measured magnetic field variation decreases in amplitude and increases in wavelength (Fig. 2b). The wavelength increase is most easily seen when the amplitude decrease is removed by rescaling the individual profiles so they have the same peak-to-peak amplitude (Fig. 2a).

Ideally the survey aircraft maintains a constant ground clearance during the acquisition of the data, referred to as “drape” flying. In practice, aircraft are subject to the effects of wind and turbulence and the inaccuracies of human control. In addition, all aircraft have a limited ability to maneuver, especially climb. Figure 3 shows the flight path of a fixed-wing aircraft across a ridge and adjacent areas. When short wavelength variations in topography (B on the diagram) are encountered, the aircraft cannot respond quickly enough to maintain the separation and positive relief will bring the magnetic sources closer to the sensor, with a corresponding increase in the amplitude of the magnetic field (c.f. Fig. 2), and vice versa. When large topographic features are encountered (A on the diagram) the aircraft will inevitably vary its ground clearance because of its limited ability to climb and to a lesser extent descend. If, as is the normal case, alternate flight lines are flown in opposite directions, adjacent parts of survey lines will have markedly different ground clearance adjacent to topographic features. This will introduce spurious variations into the data.

Current practice is to “program” a preplanned flight path for the aircraft, which the pilot follows using a real-time display. This program accounts for the terrain and the aircraft’s performance. The aim is to achieve the best “loose drape,” whereby terrain clearance effects are

minimized as far as is practical. Note that even if a perfect drape was achieved, the effects of terrain would not be totally removed because even in the ideal scenario there are still the effects of variations in the distances to magnetic materials because it is not just the materials directly below the aircraft that are influencing the measurements. The measurement at X in Fig. 3 will be affected more by the magnetic materials to the side than beneath because of the lesser distance to these materials, although this scenario only occurs in severe terrain.

Survey Design

Sampling theory requires individual measurements of TMI to be spaced at a maximum of half the wavelength of the shortest wavelength of variation. Economic and safety factors mean this is rarely practical and some aliasing of responses is the norm. This is not necessarily a major problem since during qualitative interpretation of the data it is relative changes in amplitude and texture that are used, and in fact accurate definition of the variations is only required when specific anomalies need to be analyzed quantitatively (see ► “[Magnetic Anomalies: Interpretation](#)”) and often there is a follow-up, more detailed, survey of the area of interest to improve anomaly characterization.

Survey Specifications

The survey geometry, illustrated in Fig. 1, requires definition of three key parameters: the survey line spacing and

Magnetic Methods, Airborne, Table 1 Typical survey specifications for aeromagnetic surveys

Survey line spacing (m)	Tie-line spacing (m)	Flight height (m)	Sampling ratio: Survey/Tie line ^a	Shortest along-strike wavelength sufficiently sampled
50	500	40	7.5	100
100	1000	50	15	200
200	2000	60	30	400
400	4000	80	60	800

^aAssumed flight speed is 240 km/h (67 m/s) and 10 Hz sampling resulting in a 6.7 m along survey line sampling interval. These parameters are typical for a survey with a fixed-wing aircraft

orientation and the flight height. Typical values of two of these variables for different survey types are given in Table 1. Note that the tie-line spacing is a dependent variable, typically being set to ten times the survey line spacing, although this may be reduced to five times or less for high resolution surveys.

The survey line spacing controls the cost of the survey, which for fixed-wing aircraft is based on the total length of lines flown. The total line length of a survey in terms of the survey area and line spacing can be estimated from the equation below (Brodie 2002):

$$\text{Total line length} = \frac{1000 \left(1 + \frac{\Delta_{\text{Survey lines}}}{\Delta_{\text{Tie lines}}} \right) \text{Survey area}}{\Delta_{\text{Survey lines}}}$$

where $\Delta_{\text{Survey lines}}$ and $\Delta_{\text{Tie lines}}$ are the survey- and tie-line spacings in meters, respectively, the total line length is in kilometers, and the survey area is in square kilometers.

To this cost must be added nonproduction costs such as mobilization and “stand by” costs associated with factors outside the acquisition company’s control, for example, bad weather, magnetic storms. With helicopter surveys the time spent in the air is also taken into account, and may be significant in mountainous areas where weather conditions severely restrict data acquisition both in terms of flying time and location (Mudge 1996).

It is clear from Fig. 2 that the lower the flight height, the greater will be the amplitude of the targeted responses and also the shorter the wavelength of variation, and hence the greater the ability to resolve adjacent features. Figure 2 implies the lowest possible flight height should be used, but safety considerations mean flight heights are some tens of meters. “Crop-duster” fixed-wing aircraft or heli-borne surveys may fly lower but ultra-low flying is not necessarily an advantage from a technical point of view since it means maintaining consistent terrain clearance is more difficult. Besides, there may be very shallow magnetic sources whose anomalies mask those of deeper, more significant variations (Doyle and Lindeman 1985).

Reid (1980) showed that accurate definition of a TMI anomaly requires the sample spacing to be a maximum of half the source-sensor separation. The combination of the

rate at which the aircraft’s magnetometers make a measurement (typically 0.1 s) and the velocity of the aircraft (typically 220–280 km/h for a fixed-wing aircraft) result in an along flight line sample spacing of about 7 m for fixed-wing aircraft. Helicopter surveys with a 0.1 s sampling typically have a 4–5 m spacing, but the trend is to employ faster sampling magnetometers, reducing this spacing to even less. The important outcome from the above is that the along-line sampling exceeds the requirements of sampling theory for practical flight heights, and the variations in TMI in the direction of the flight path can be considered as more than adequately characterized. The same is not true for variations in the directions perpendicular to the survey line direction because, as shown in Table 1, the spacing of these lines is very much greater than the along-line sampling interval. Note that since anomaly wavelength decreases with source-sensor separation, a low flight height combined with wide survey lines will lead to greater aliasing in the direction perpendicular to the survey lines. This is reflected in the parallel increase in flight height with line spacing in Table 1.

Conventionally airborne geophysical surveys are flown with the flight lines oriented perpendicular to the dominant geological strike direction. The rationale for this is that there will be shorter wavelength variations across strike than parallel to strike, and hence the greatest sampling density should be in the strike-perpendicular direction. For elongate anomalies the short wavelength variation parallel to strike is small, so significant aliasing does not occur. In practice economic considerations dictate the survey line spacing, meaning there is inevitably some aliasing of TMI variations in the direction perpendicular to the survey lines.

Even if there is some variation in the strike across the survey area, and there is also a conflict caused by variations in stratigraphic and structural strike, it is best to use a single-line orientation. If this is not the case the data are very difficult to process into an easily interpreted form.

For surveys in equatorial regions the east–west elongation of magnetic responses associated with low declinations (<30°) means it is always preferable to fly surveys with north–south survey lines.

Data Processing

The term data processing refers here to the removal of noise prior to enhancement (see ► [“Magnetic Data Enhancements and Depth Estimation”](#)) and interpretation of the data (see ► [“Magnetic Anomalies: Interpretation”](#)). The aim of the processing is to create an instantaneous “snap shot” of TMI variations across the survey area with the contribution from the geomagnetic field removed. It is normal practice to complete at least preliminary processing in the field to ensure that the data are of acceptable quality.

The main source of noise in aeromagnetic data is temporal changes in the Earth’s magnetic field, which occur during the course of the survey and hence from the mobile sensor’s perspective are indistinguishable from spatial variations in TMI due to the geology of the survey area. It is to determine such variations that the repeat measurements inherent in the survey/tie-line geometry are required (Fig. 1), along with the TMI time series recorded by each base station.

The removal of the noise is achieved in a series of steps. Figure 4 shows a raster display of an aeromagnetic dataset

after each of the processing steps described below. Figure 4a shows the data after compensation for aircraft-related effects. Note the dominant characteristic is a north–south striping (corrugations) with a wavelength approximately equal to twice the line spacing; this being primarily the result of the temporal changes in the geomagnetic field during the survey and deviations of the aircraft from the ideal flight path.

Correction for Temporal Changes in the Geomagnetic Field

The Earth’s magnetic field varies in intensity at a range of time scales; see ► [“Geomagnetic Field, Theory”](#). Of significance to aeromagnetic surveys are magnetic storms (during which surveying must be discontinued) and micropulsation and diurnal variations (see ► [“Electromagnetic Pulsations and Magnetic Storms”](#)). Micropulsations are variations in the geomagnetic field that last from a few seconds to a few minutes. They change in both phase and amplitude over distances comparable to survey dimensions. Diurnal variations have periods of 24 h and magnitudes of up to about 50 nT.

Magnetic Methods, Airborne, Fig. 4 Gridded TMI data from an aeromagnetic survey in Australia. The colors represent changes in amplitude (hot colors high, cold colors low) and the intensity represents a shaded relief presentation designed to highlight north–south trending features. (a) Data after compensation for magnetic fields originating in

the aircraft. (b) As for (a) but with correction for temporal variations in the geomagnetic field as measured by a base station magnetometer. (c) As for (b) but with international geomagnetic reference field removed and tie-line leveling corrections applied. (d) As for (c) except for micro-leveling. Images created by Cowan Geodata Services

The principal means of removing micropulsation and diurnal variations is the base station magnetometer readings (the base station readings also allow the recognition of the occurrence of a magnetic storm). The readings in the aircraft and base station are time synchronized. In theory the variation at the (stationary) base station should represent geomagnetic field variations that occur during the course of the survey, and subtracting the base station readings from the time equivalent survey reading should leave a residual dataset free of the temporal variations. However, this is an imperfect process since the amplitude and phases of the changes vary with location. To counter this multiple base stations may be used for large surveys. The subtraction causes a base line shift in the data but this is unimportant since it is relative variations in TMI that are required for interpretation of the data (see ► [“Magnetic Anomalies: Interpretation”](#)). Often an average intensity of the magnetic field in the survey area is added to each measurement to return the data to closer to likely absolute values. Figure 4b shows the magnetic dataset after corrections for temporal changes in the geomagnetic field derived from a base station dataset. The degree of striping in the data is significantly reduced, although it is not eliminated.

Removal of Geomagnetic Field

It is normal practice to remove spatial variations in TMI caused by the geomagnetic field as defined by the International Geomagnetic Reference Field (IGRF), see ► [“Geomagnetic Field, IGRF”](#). The wavelengths of variation of the field are very large compared to survey dimensions, and subtraction from the observed data will not usually significantly affect variations of interest. Nevertheless it is standard practice to remove such variations.

Tie-Line Leveling

Ideally the processing described above will mean the TMI measured along the survey- and tie-lines at their cross-over points will be identical. In practice, there will always be mismatches because of the imperfect aircraft compensation, spatial variations in diurnal and micropulsation-related changes, but also because there are uncertainties in the aircraft's position, that is, where the cross-over occurs within the datasets. Differences in elevation between the survey- and tie-line measurements are the main source of error.

The minimization of the differences at the cross-over points is referred to as “leveling.” Various approaches are used but normally there is an initial estimate of the extent to which location errors are responsible for the differences. Once these are accounted for the remaining differences at each line intersections are used to adjust the amplitudes

along the survey lines. The most common method involves fitting a smooth function to the differences and using this to estimate leveling “corrections” at each measurement point along the survey lines. Figure 4c shows the magnetic data after removal of the IGRF (minimal effect) and tie-line based leveling. Corrugations in the data are now all but invisible.

Microleveling

Microleveling is a loosely defined term for making adjustments to the data when the processing stream outlined above is complete and artifacts appear to remain in the data. The details of these methods are mostly proprietary but are all various forms of low-pass filtering. The filter characteristics are often defined by the flight and survey line spacing, for example, Minty (1991). Microleveling is usually applied after the data have been gridded (see below), and the correction so derived used to adjust the individual survey measurements prior to re-gridding. Figure 4d shows the example magnetic data after application of a commercial microleveling process. There is some improvement in the lateral continuity of anomalies.

Gridding

By far the most common form of display and input to enhancement oriented processing operations are data projected on to a regular grid. Gridding the data is a compromise between honoring detailed sampling along the survey lines and producing smooth interpolation into areas between lines where no readings have been made. The grid cell size, that is, distance between interpolated locations, is conventionally between 1/3 and 1/5 of the survey line spacing. The loss of information in the survey line direction is balanced by an acceptable degree of reliability of interpolated points located between the survey lines. Nevertheless, especially with greater survey line spacing, aliasing frequently causes laterally continuous features to appear as a series of adjacent subcircular features, referred to as “beads.” This effect becomes worse as the trend of the anomalies approaches that of the survey lines.

Discussion of Data Processing

The processing described above is a combination of processes with a basis in field measurements and processes requiring the judgment of an expert processor, because it is not practical to collect the necessary data to process the data perfectly. There is no way to reliably judge the accuracy of the final measurements, but an accuracy of ± 1 nT is often quoted for individual points in the gridded datasets.

Summary

Mapping variations in TMI allows variations in rock magnetism in the upper crust to be mapped, from which geology may be inferred. Measurements of TMI made by sensors mounted on helicopter or fixed wing crafts allow rapid and efficient acquisition of data. The main sources of noise in magnetic data from airborne platforms are temporal changes in the geomagnetic field and variations in the distance between magnetic sources and the magnetometer caused by changes in aircraft ground clearance. Temporal changes are accounted for by comparing survey data with readings contemporaneously recorded by a magnetometer on the ground. Discrepancies in repeat readings at the same location allow any remaining temporal change noise to be removed along with corrections for variations in survey altitude. The resulting data are projected on to a regular grid for display as raster images.

Magnetic Methods, Principles

Kusumita Arora

National Geophysical Research Institute, Council of Scientific and Industrial Research (CSIR), Hyderabad, India

Definition

Magnetic Methods, Principles provides an overview of the various approaches, which generate knowledge of the different aspects of the Earth's magnetic field.

Introduction: Magnetic Field on Surface of Earth

Magnetism makes us think of a flat iron needle, which aligns itself in the north-south direction. Or it makes us think of a bar of iron, which is able to attract other pieces of iron. Essentially magnetism is a force, which can attract (or repel) another magnetic object. The property of magnetism as manifested by certain types of rocks was known to the ancient Greeks and Chinese and was used by early travelers for direction finding when stars were not visible.

Systematic study of the Earth's magnetic field and its variations started in the thirteenth century in Europe, largely based on the behavior of the compass needle, which responds to the complete magnetic force at each location of measurement. This was followed by observations at different times of the day, year and so on. The behavior of magnetic needles at different locations on the Earth's surface led to the proposal by William Gilbert around 1600 that the Earth itself was a giant magnet, which was the beginning of studies of the geomagnetic field. More than two centuries later Hans Christian Oersted observed that flow of current in a wire caused a magnetic needle to deflect. Andre Marie Ampere established that magnetism was a force generated between two electric currents; two parallel currents in same direction attract and in opposite direction repel. Later it was demonstrated that properties of bar magnets were very special cases of the same phenomenon: within magnetic materials, bulk magnetism is the result of the motion of electrons in an atom, which sets up a magnetic field around itself.

The first magnetometer was the compass, which was used to measure the direction of the field; an instrument to measure the intensity was developed in 1833 by Gauss. Vector magnetometers, which can measure the intensity of the field in three orthogonal directions came into existence during the nineteenth century. There was several fold increase of sensitivity in measurements of the strength, changes of the three

components, and the absolute directions respectively (more details can be found in article ► “[Magnetometers](#)” in this volume). With data recorded over time, it was observed that the magnitude and direction of the magnetic field changes at different locations of measurements; the magnitude and direction also change at the same location with time, sometimes irreversibly, at other times regaining the original values. It is now known that from local to global, the changes of Earth’s magnetic field cover about 7 orders of magnitude in space and about 17 orders of magnitude in time, from under a second to close to the age of the Earth (Courtillot and Le Mouél 1988).

The Earth’s steady magnetic field is produced by many sources, both above and below the planet’s surface. These include the geomagnetic dynamo in the outer core, crustal magnetization, the ionospheric dynamo, the ring current, the magnetopause current, the tail current, field-aligned currents, and convective, electrojets. Comprehensive information can be found in Mande et al. (2019). Thus, the magnetic field measured at a point on the Earth’s surface is a combination of several components (Amory-Mazaudier 2008):

$$B = B_c + B_e + B_{in} + B_a$$

Where B_c = main/core field; B_e = external field (due to ionospheric and magnetospheric sources); B_{in} = induced field generated by the external field B_e ; B_a = magnetization field (due to the magnetization of the rocks in the lithosphere).

To study each of the above, a variety of observational and corresponding computational techniques are employed. Prevalent directions of research are based on four types of data:

- The time series of variations in scalar intensity and the vector magnitude and directions of three perpendicular components, at different locations on the surface of the Earth.
- The spatial variations of scalar intensities at closely located intervals in land and oceans
- Variations of three components of magnetic (commonly along with electric) field at stations of regular intervals
- Measurements of magnetic memory of rocks of different ages, which preserve signatures of the geomagnetic field, generated 3.45 billion years ago

Major Aspects of Probing the Geomagnetic Field

Core/Main Field and Its Changes

Developments in Observational Methods

First observations of the main field characteristics based on the compass needle can be traced to the concept of declination, which began to take shape from the thirteenth century (Chapman and Bartels 1940), while that of inclination was

formalized in the sixteenth century (Norman 1581). The idea of Earth’s magnetic poles took shape and were formalized by William Gilbert and his student Mark Ridley, who established the relationship of inclination and latitude (Jonkers 2000). Le Nautonier documented the variations of declination with longitude (Mande et al. 2019).

The quality and quantity of measurements of the full field vector at specific locations on the Earth’s surface, evolved through time from early nineteenth century to present day sustained precision measurements of vector and scalar components of the field at fixed locations all over the globe, called *Magnetic Observatories*. Observatory measurement systems consist of continuous measurements (quite commonly at 1 Hz) of the variations of the three components of the magnetic field along with continuous measurements of the scalar measurements (again at 1 Hz) of the total field. Daily/bi-weekly/weekly measurements of the absolute values of inclination and declination are further measured manually. The three datasets are combined together to produce continuous absolute values of the three components of the geomagnetic field at the particular location. Measurements at Observatories are sustained typically over decades and even centuries; the first Observatories were setup in the middle of the nineteenth century and at present we have around 200 networked Observatories (<https://www.intermagnet.org/>), which record the transient and long-term changes of the field. By combining data from observatories all over the world, it is possible to map the Earth’s magnetic field and study its spatiotemporal changes.

The first discoveries of changes of the Main field (called Secular variations) happened during the seventeenth century (Jonkers 2000). Changes of declination with time at a fixed location was noted as early as 1622, while that of inclination was found some years later. Data from Magnetic Observatories showed that all components of the Earth’s magnetic field change with time, from years to millennia. From the early twentieth century networks of *magnetic repeat stations* were established, in addition to Magnetic Observatories. Repeat stations are precisely located points on the Earth’s surface, where the three components of the geomagnetic field are regularly (yearly to once in 5 years) measured to the highest possible accuracy (Newitt et al. 1996). Most countries have their own networks of repeat stations and combined with the data from observatories monitor the annual/decadal/centennial changes of each component of the magnetic field in the region.

European merchant and naval ships, later followed by research vessels sailing through the Atlantic, Pacific, Indian Oceans provided a rich source of magnetic field measurements on the surface (Jackson 1992) (more details can be found in articles ► “[Geomagnetic Field, Measurement Techniques](#)” and ► “[Magnetic Methods, Surface](#)” in this volume). Edmond Halley published the world’s first magnetic

map of the Atlantic Ocean in 1701 showing lines of equal magnetic declination, collected during two sea voyages. From these beginning, global maps of the main geomagnetic field were generated using decades of data from Magnetic Observatories (more details can be found in article ► [“Geomagnetic Field, Global Pattern”](#) in this volume). The last few decades of global measurements by satellite have enabled major leaps in mapping of this field and its short-term and long-term changes; it is now possible to calculate geomagnetic secular variation models of unprecedented spatial resolution without using repeat station measurements (more details can be found in article ► [“Magnetic Methods, Surface”](#) in this volume).

Resulting Knowledge

In 1833, the studies of Carl Friedrich Gauss led to the idea that the geomagnetic field could be approximated by a magnetic dipole, which has its origin inside the Earth. Currently it is tilted at an angle of about 11° with respect to Earth's rotational axis. The magnitude of the Earth's magnetic field at its surface ranges from 25,000 to 65,000 nanoteslas from Equator to Poles. Gauss also demonstrated that the dipolar component was inversely proportional to the square of the distance. Observatory data along with archaeomagnetic measurements indicate that the strength of the dipole field has been decreasing since the last 2000 years and it now is only about half of what it was two millennia ago. At its present rate of decrease, the strength would reach zero in approximately 1600 years or it might start to increase again sometime in the future.

Secular Variation is not constant in time, it also varies from place to place. Analyses of the variations show that most of it can be described in terms of three processes:

- A decrease in the strength of the dipole part of the magnetic field
- A westward drift in the non-dipole part of the magnetic field
- Changes in the non-drifting part of the non-dipole field

First suggested in the early twentieth century (Larmor 1919), it is generally recognized that the Main/Core field is created by the “dynamo action” of convective fluid motions in the Earth's electrically conducting outer core, subjected to rapid rotation. Various theories based on computations of rotating fluid dynamics and magnetohydrodynamics have evolved over past decades, which attempts to explain the nature of the geomagnetic field and its changes; concept of buoyancy gradients (thermal or compositional) is used to drive and sustain the geodynamo (Hollerbach 1996 and references therein). Kono and Roberts (2002) presented an exhaustive comparative analysis of different geodynamo models propounded by researchers; the dominance of the axial field; drift of the field, secular variations, and even polarity reversals have been simulated in most of the models

and broadly match the known data. In recent developments, Blanc et al. (2020) have used thermochemical modeling to suggest that crystallizing magma ocean in the Earth's mantle is a plausible mechanism to sustain an early magnetic field.

External Field

Developments in Observational Methods

Short term variations of the field, were discovered in the first quarter of the eighteenth century. In 1722, George Graham discovered the diurnal variation of declination. In 1716, Halley connected disturbances of the Earth's magnetic field with the occurrence of an aurora over London, in 1741, Graham in London and Andreas Celsius in Uppsala observed simultaneous perturbations, which would later be identified as the polar aurora (Canton 1759). Superimposed on the regular daily variation of the magnetic field are irregular variations during disturbed magnetic days. These have many different signatures on the magnetic records, also depending on the latitude of the location of observation. Examples of such signatures in daily magnetograms from the low latitude Magnetic Observatory of Hyderabad (HYB) can be found in the figure below. On examination of data from magnetic observatories, it was evident that changes in amplitudes of the geomagnetic field, which recovered to original values could span over a few minutes to 11 and 22 year cycles (Cliver 2015). With the availability of the vast dataset from dedicated satellite missions, it became possible to analyze the global patterns of external field changes (Friis-Christensen et al. 2006; Xiong et al. 2016; Fathy et al. 2019; Kim et al. 2019).

Resulting Knowledge

The Earth's magnetic field, which is the strongest one among the rocky planets, extends 36,000 miles into space, created by the action of the geomagnetic dynamo, without which neither the geomagnetic field nor the other sources would exist. Not far above Earth's surface the effect of other sources becomes as strong as or stronger than that of the Main/Core field. The Earth's magnetosphere is the spatial domain of the magnetic field lines that connect to the Earth and is the region of space where the earth's magnetic field plays a controlling role on various particles and radiations found there. Details of its structure started emerging from the early twentieth century with the advent of satellite observations. The magnetosphere would be a magnetic dipole but is distorted under the influence of magnetized solar wind, compressing it on the dayside. Solar activity controls the changes of the external field through two main kinds of interaction processes: energy transfer between the solar wind and the magnetosphere, and ionization of the E-Layer in the ionosphere (Gavoret et al. 1986). The interactions of the magnetosphere with the electromagnetic forces and emissions from the Sun's magnetic field, produces the ionospheric dynamo, the ring current, the

Magnetic Methods, Principles, Fig. 1 HYB daily magnetograms showing signatures irregular variations associated with magnetic storms

magnetopause current, the tail current, field-aligned currents and the electrojets. Each of these current systems are associated with a corresponding magnetic field, which are superposed on the Main field.

Explanations of the observations of the regular variations of the Earth's magnetic field on all the days at the sunlit side of the Earth started in the late nineteenth century. In situ measurements of neutral atmosphere motions and ionospheric electric currents began during the twentieth century, using on the measurements of rockets, meteoric radars, and Incoherent scatter sounders. The regular variations are attributed to the current systems of the ionosphere. These currents are generated by the motion of the atmosphere which drags preferentially the ions through the Earth's magnetic field lines in the E region dynamo ($100 \text{ km} < h < 150 \text{ km}$) and cause a differential drift between ions and electrons. The effect of this daily regular *ionospheric dynamo* is manifested as a diurnal pattern in the daily magnetograms of Observatories (Fig. 1). Electrojet currents, which travel around the E region of the ionosphere from 100–150 km altitudes are Hall currents primarily carried by electrons, which occur in the Equatorial and Auroral regions of the Earth's magnetic field. The auroral electrojets, which have typical amplitudes of 100–1000 nT, may reach upto 3000 nT during intense geomagnetic storms and also shift equatorward (e.g., Feldstein et al. 1997; Ahn et al. 2000). The eastward component of the electrojet flows in the afternoon sector and terminates in the premidnight region where it joins the westward component. The westward electrojet flows through the morning and midnight sectors and typically extends into the evening sector along the poleward border of the auroral oval where it diverges as upward field-aligned currents. The Equatorial Electrojet causes a magnetic field disturbance of the horizontal component of the terrestrial magnetic field at the Earth's surface over a distance of about 600 km across the dip equator with maximum amplitudes of the order of 50–100 nT being superposed on the Sq (Hamid et al. 2014).

Works of many scientists during the twentieth century resulted in the mapping of the magnetospheric currents and understanding of their imprints on the magnetic field (Ganushkina et al. 2018). Signatures of ionospheric and magnetospheric currents on the daily magnetograms of a typical magnetic observatory are shown in Fig. 1; seasonal and solar cycle patterns of such signatures during geomagnetic quiet conditions have been discussed in details by Olsen and Stolle (2017). Energization of the ring current by storms or substorms causes a worldwide depression of the regular daily field over several hours to days, which later recovers (Williams 1985; Zhao et al. 2015) its original trends. Characteristics of field-aligned currents (FAC) associated with substorms were studied from data of Traid and subsequent satellites. During storms and substorms the average latitude width of these currents increases by 20–30% and the centers of these regions shift equatorward by 2° – 3° with respect to the quiet time values, with corresponding reflections in the magnetic records. The FAC is the primary source for the eastward-westward magnetic field perturbations at high latitude (Adhikari et al. 2017). Ultralow frequency magnetic pulsations originate from magnetospheric processes, playing a major role in magnetospheric dynamics and energy transport; they appear as near sinusoidal or irregular fluctuations in the magnetograms at ground recording stations/Observatories, as shown in red box in Fig. 2. Satellite based measurements of the magnetic field perturbations, associated electric field and particle density have allowed study of spatial distribution and propagation mechanisms of pulsations (Anderson 1990). Waves of different frequencies and polarizations originate in different regions of the magnetosphere and are controlled by the solar wind dynamic pressure and magnetic field; changes in orientation of the interplanetary magnetic field or an increase in solar wind velocity have strong influence on the type of waves (McPherron 2005).

Magnetic Methods, Principles, Fig. 2 Pulsation observed at low latitude Observatory

Lithospheric Field

Developments in Observational Methods

The property of magnetism exhibited by some rocks have been known since the time of ancient Greeks and Chinese; compasses were observed to deflect from their original orientation, when placed near such matter. Such rocks found in the crust and upper mantle produce the Lithospheric field. The attraction of compass needles (dipping needles) to natural iron formations and their association with base metal deposits emerged during the nineteenth century, pioneered by efforts in Sweden. By the early twentieth century, it was understood that rocks that have magnetically susceptible minerals, like magnetite, acquires magnetic properties of their own under the influence of the ambient field (the phenomenon is called ferromagnetism). Regions hosting such magnetic rocks/minerals within the crust produce a positive magnetic anomaly, viz., enhanced values compared to that of surroundings. With advances in instrumentation and data acquisition techniques, airborne magnetic measurements were made from a balloon in 1910. There was intensification of efforts for airborne submarine detection during World War II (Reford and Sumner 1964; Hanna 1990), which brought in a new era of airborne magnetic surveys, both for the exploration industry and for countries to map regional geology at national scales (Hanna 1990; Hood 1990). Some of the first aeromagnetic maps were published in 1946. The techniques were soon adapted for marine use. In 1955 the first 2D marine magnetic survey

was conducted off the coast of southern California in the eastern Pacific Ocean (Mason 1958). This marine magnetic survey revealed the pattern of magnetic stripes offset by a fracture zone, which were later attributed to seafloor spreading during periods of geomagnetic reversals (Vine and Matthews 1963; Morley and Larochelle 1964). More details may be found in ► “Magnetic Methods, Surface” in this volume.

The proton precession magnetometer was developed in 1955, followed by the optically pumped and SQUID magnetometers during the late 1990s; later magnetic gradiometers were designed. Parallely major computational techniques were developed to remove the effects of the ambient geomagnetic and solar magnetic fields and isolate and study the local magnetic anomaly maps for the depths and dimensions of the subsurface source bodies (Nabighian et al. 2005). Efforts over the last few decades have been focused on producing a global, near-surface map of the crustal magnetic field of the Earth. This map includes data from airborne, shipborne, terrestrial as well as satellite (MAGSAT, OERSTED, CHAMP, SWARM) measurements (Lesur et al. 2016).

Resulting Knowledge

Anomaly maps depicting crustal magnetization represent the cumulative effects of the earth’s magnetic field from the time of formation of the rocks within the crust, through various stages of metamorphism and finally the present ambient field. As the main field of the earth changes its strength and direction over millions of years, these influences are imprinted

cumulatively on the magnetization patterns of the minerals in the rocks. Metamorphism, petrology and redox state all have important effects on the magnetism of crustal materials. Mapping of the crustal magnetic field provides a third dimension to surface observations of the Earth's composition and geologic structure, aided by the suite of mathematical tools developed to assist with their interpretation. Studies of crustal magnetism have contributed to geodynamic models of the lithosphere, geologic mapping and petroleum and mineral exploration.

The crustal/lithospheric field originates in iron-bearing rocks near the Earth's surface (upper 20–30 km) where temperatures are sufficiently low, i.e., less than about 580 °C (the Curie temperature of magnetite). Hence it provides insight into the distribution of magnetic minerals within the crust, which represent the magnetism at great pressure and temperature for plutonic rocks, the metamorphic environment for altered igneous and sedimentary formations, past geomagnetic fields for volcanic rocks. On a regional scale, magnetic anomalies illustrate terrane boundaries by a contrast in magnetic fabric at the contact. Crustal magnetization consists of two types: induced and remanent (more details available in ► [“Remanent Magnetism”](#) in this volume). Induced magnetization is the signature of the present geomagnetic field; it is proportional to the strength of the inducing field and vanishes when the primary field vanishes. Remanent magnetization is produced by a primary field, but once created it persists after the primary field has disappeared, depending on the concentration of ferromagnetic minerals in the rocks.

Detailed magnetic surveys continue to be a primary tool for locating favorable host rocks for potential mineralized zones, faults, hydrothermal sources and for general geologic mapping. It is frequently used to study basin structure and map basement features below, which may be favorable for hydrocarbon accumulation. Magnetic methods are also used for environmental contamination issues, seismic hazards, landslide hazards, archaeological mapping and so on.

Induced Field

Methods to Study Subsurface Conductivity Structure

The phenomenon of electromagnetic induction was first discovered in the 1830's by Michael Faraday, who observed that when he moved a permanent magnet in and out of a single loop of wire it induced a voltage and a current was produced i.e., by changing the magnetic field an electric current can be generated, the strength of which is proportional to the rate of change of flux. This led to the law linking electricity with magnetism: Faraday's Law of Electromagnetic Induction.

During space weather events, the electric currents in ionosphere and magnetosphere experience rapid fluctuations causing corresponding variations in the magnetic field. The time varying magnetic field induces telluric currents in the

ground to create a secondary magnetic field, which is location dependent; the electrical conductivities of the local rock formations will determine the current strength, which tends to reduce the amplitude of the Z component and enhance the magnitude of the H component. The generation of induced fields is in effect the influence of external fields on lithospheric fields, as most commonly the geological entities having higher magnetism tend also to be more conductive.

Early researchers applied this principle to investigate phenomenon of electromagnetic induction within the Earth, generated by the variability of the geomagnetic field, starting from the second half of nineteenth century. This is called the magnetotelluric (MT) method. The Earth's naturally varying electric and magnetic fields are measured over a wide range of frequencies from 10,000 to 0.0001 Hz. The ratio of the electric field to magnetic field provides simple information about subsurface conductivity. Due to the skin effect, the ratio at higher frequency ranges gives information on the shallow Earth, whereas deeper information is provided by the low frequency range. The ratio is usually represented as both apparent resistivity and phase as functions of frequency. MT measurements can investigate depths from about 300 m down to hundreds of kilometers. The vertical resolution of MT mainly depends on the frequency being measured whereas horizontal resolution of MT mainly depends on the distance between sounding locations.

Geomagnetic depth sounding (GDS) or magnetovariational studies (MVS) are also conducted at large periods of magnetic variation data, whereby different kinds of transfer functions are used to calculate the subsurface conductivity structure. GDS has much longer periods than MVS; the calculations for the former use a spherical Earth model. Large scale conductors at upper mantle depths can be detected, which contribute to the study of tectonics. More will be found in ► [“Magnetotellurics, Crustal Imaging”](#) of this volume.

The oceans play a special role in this induction due to their relatively high conductivity, which leads to large lateral variability in surface conductance. Electric currents that generate secondary fields are induced in the oceans by two different processes: (a) by time varying external magnetic fields, and (b) by the motion of the conducting ocean water through the Earth's main magnetic field. As the electrical conductivity of both seawater and material under the oceans differs considerably from that of the continents, an enhanced effect usually referred to as the “geomagnetic coast effect” (GCE) is observed at data from such locations.

Methods to Study Geomagnetically Induced Currents (GIC) in the Earth's Surface

The same space weather events also induce currents (GIC) in conductors on the surface of the Earth, most commonly electric transmission grids, buried pipelines and cables, railway

tracks. GIC were first observed on the emerging electric telegraph network in 1847–1848 during storm events of Solar cycle 9 (Ronalds 2016). Explosion in various conducting networks have made the significance of GIC greater in modern society. The effect is stronger at higher latitudes and have been studied for necessary mitigation measures in Canadian, Finnish and Scandinavian power grids and pipelines since the 1970s (Thomson et al. 2005). GIC of tens to hundreds of amperes have been recorded. GIC have also been recorded at mid-latitudes during major storms. There may even be a risk to low latitude areas, especially during a storm commencing suddenly because of the high, short-period rate of change of the field that occurs on the day side of the Earth.

Paleo Field

Developments in Observational Methods

It was discovered in the nineteenth century that minerals in ancient rocks can become magnetized parallel to the Earth's magnetic field; this property enabled researchers determine the orientation and intensity of Earth's magnetic field back through time. As rocks form and cool, the electrons within individual grains can shift in the direction of the surrounding magnetic field. Once the rock cools past a certain temperature, known as the Curie temperature, the orientations of the electrons become permanent. Scientists can determine their age and use standard magnetometers to measure their orientation, to derive the strength and orientation of the Earth's magnetic field at the point in time when this characteristic was acquired. Details of this approach are provided in “► [Paleomagnetism, Principles](#)” of this volume.

Direct measurements of magnetic properties of basalts as well as other igneous, metamorphic and sedimentary rocks revealed the differences in their magnetic properties (Faujas de St-Fonds 1788; Fournet 1848). Laboratory experiments of de-magnetizing and remagnetizing materials like iron, led to the concepts of remanent and induced magnetization (Mellon 1853a, b) and also established that direction of magnetization coincides with that of the applied field and not of the crystallographic axes of the rock material (Sidot 1868). Observations of magnetic properties of man-made items like bricks could produce information about magnetic field of more recent times (Folgheraiter 1899), an approach which led to the discipline of Archaeomagnetism.

Resulting Knowledge

Based on measurements on selected quartz crystals from the Greenstone Belt of the Kaapvaal craton of South Africa, it has been inferred that a magnetic field half as strong as today's existed 3.2 billion years ago and a field of strength about 70% of the present existed 3.45 billion years ago (Tarduno et al. 2010). More recently, analyses of zircons from the Jack Hills

(Western Australia) provide evidence for a geomagnetic field 4.2 billion year old, just a few hundred million years after the lunar-forming giant impact (Tarduno et al. 2020), although other scientists still debate this issue.

The geomagnetic field played a vital role in protecting the planet from damaging solar radiation, which may have stripped it of its atmosphere and water, making it completely unsuitable for life as we know it. Knowledge of its changes with time allows a window into the changes of the Earth's core, which in turn tell us about the thermal evolution of the planet. Knowledge of the early field could also inform us about the conditions in which the first life forms appeared.

Early in the twentieth century, Bernard Brunhes (1906) found that some rocks are magnetized in the opposite orientation to the Earth's present-day magnetic field. This led him to propose that the Earth's magnetic field had reversed its polarity in the past. These reversals have subsequently been shown to be non-periodic and the Earth's magnetic field reversal history is now well known for the past 175 million years and more approximately understood to the beginning of the Paleozoic (ca. 545 Ma), based on evidences from rocks, which preserved these signatures. The most recent Matuyama-Brunhes reversal, which marks the Lower-Middle Pleistocene boundary, has been identified in dozens of marine sediment cores, exposed sedimentary successions and a few lava flow sequences (Singer et al. 2019 and references therein). Details can be found in ► “[Paleomagnetism, Measurement Techniques and Instrumentation](#)” of this volume.

Summary

The physical phenomenon of magnetism is one of the oldest subjects of study by humans. This article has tried to provide an overview of the major approaches which investigate the various aspects of Earth's magnetism. They include investigations of the present field in all its aspects: Core/Main field, Lithospheric field, External field, Induced field, as well the studies of the origin and evolution of the field since the time of formation of the Earth. Details of each aspect have been dealt with in other articles of this volume.

Magnetic Methods, Surface

Nandini Nagarajan

National Geophysical Research Institute, Hyderabad, India

Definition

This entry describes the techniques, instrumentation, and uses of ground-based magnetic measurements on land and at sea. It includes sections on the network of Magnetic Observatories on ground, where long-term measurements of the field and its changes are observed. It also includes the techniques of land and marine magnetic surveys, which are aimed at extracting local or regional information of subsurface structure.

Magnetic Observatory

Magnetic observatories continuously measure the Earth's magnetic field at fixed locations at the Earth's surface. They are designed to operate for several decades to stably record rapid and slow variations of the earth's magnetic field and report time-averaged values that estimate the form of the Earth's magnetic field. Since observatories started operating in the nineteenth century, the methods of measurement, reporting, and analysis have varied with region and time. After the International Geophysical Year (IGY –1957–58), the quality and organization of the data have been standardized, making spatial and temporal studies easier, more refined, and consequent models more accurate. Classical torsion magnetometers, with analogue-photographic systems, were replaced in 1980s, by improved fluxgate magnetometers and digital data acquisition systems. The International Association for Geomagnetism and Aeronomy (IAGA) is the coordinating body for the magnetic observatories of the world, standardization of measurement, exchange of data, and presentation of models of the Earth's magnetic field. There are about 200 magnetic observatories reporting standardized data, and several more making continuous variation measurements with absolute control (Fig. 1).

INTERMAGNET is network (International Real-time Magnetic Observatory Network) arising out of continuing improvements in instrumentation and upgradation of magnetic standards evolved by IAGA that provides 1-min values of the three components of the geomagnetic field, in near-real time. With developments in instrumentation, data acquisition, and data dissemination, an increasing number of observatories are producing a filtered 1-s data product in addition to

Nandini Nagarajan: was retired.

Magnetic Methods, Surface,

Fig. 1 Currently operating observatories (updated in www.geomag.bgs.ac.uk)

traditional 1-min data, hourly means, daily means, monthly means, and annual means. Presently there are over 200 observatories, worldwide.

210MM is a chain of variation stations and observatories, that cover Russia, Japan, South east Asia, and Oceania along the magnetic meridian 210° . This chain has reported data from remote regions of the Southern Indian and Pacific Oceans and made seminal contributions in research. The project has also revived observatories in Africa, providing technical support.

Measurements at Magnetic Observatories

Vector and scalar measurements: Magnetic measurements can be scalar (total field) or vector. To define the vector, 3 out of 7 elements need to be measured simultaneously (Fig. 2). Commonly any three of these elements are measured in a magnetic observatory as variations, to fully define variations of the total magnetic field.

Absolute measurements: Most vector magnetometers used in magnetic observatories (earlier torsion, and recently fluxgates), usually drift in time due to several factors such as temperature variations, magnetic moment, and ageing of the electronics. In order to periodically recalibrate the vector measurements, absolute measurements fully defining the magnetic field vector are performed, to complement continuous measurements, on regular basis (typically once a week). Such measurements are made by a trained observer using a single-axis fluxgate magnetometer mounted onto a non-magnetic theodolite and a scalar magnetometer. From which, the continuous measurements can be calibrated to a baseline defined by absolute measurements. Two types of data are available from observatories: preliminary data, which are made available in quasi-real time (less than 72 h), and definitive data, which are produced only once a year, typically a

Magnetic Methods, Surface,

Fig. 2 Magnetic elements defined in geographic and geomagnetic coordinates (Jankowski and Sucksdorf 1996)

few months after the end of the calendar year. After reducing time variations to absolute baseline at a location, continuous observations of the vector magnetic field are produced at desired sampled intervals: minute, hour, daily, month, year, etc. These data are available for all years going back to the start of observations at each observatory. The format for easy assimilation and distribution of this data are formulated by IAGA working groups – updated periodically since 1957–58. This data is also available at World Data Center for Geomagnetism, established in different countries, partly by their research institutions and partly funded by IAGA.

Observations from this Data

Magnetic observatory data are used to report and study periodic, episodic, and transient variations that are classified by time scale and mechanism: Long-term secular variation,

Magnetic Methods, Surface, Fig. 3 Diagram showing the different types of geomagnetic variations (Okeke et al., <http://www.sao.ac.za/~wgssa/as4/fokeke.html>)

11-year solar cycle, annual, semi-annual, seasonal, and daily variation and variations over minutes to days, classed as disturbances (Fig. 3).

Observatory yearbooks often give the average solar daily variation for different months of the year, and even separately for quiet, disturbed, and all days. Based on an analysis of magnetic activity by trained observers, and estimation of the activity indices (most commonly K), five quiet and disturbed days are selected for each month by the International Service of Geomagnetic Indices.

Magnetic variations have characteristics, varying over latitude and over a wide range of periods attributed to different sources – solar activity – from 11 year to 27 days, diurnal harmonics of ionospheric currents from 24 to 4 h, shorter events like sudden commencements, sudden impulses, substorms (bays) -2 h to 1 min, magnetic pulsations, with small amplitude and short periods, from 1 to 60 s. Hourly and daily variations are a measure of solar interaction with the Earth's magnetic field. This can be both solar radiation interacting daily with the ionosphere or corpuscular streams interacting with the magnetosphere, manifested as disturbances. Regular solar daily variation is also a function of season, solar activity and latitude. The variation of the magnetic field on magnetically quiet days is called the solar quiet day variation or Sq variation. Magnetic storms (~day), substorms (~hour), pulsations (~min), sudden impulses, and solar flares are some of the transient disturbances. Modelling the fast and slow variations of the Earth's magnetic field has made rapid strides. Currently, it is possible to access models, based on studies of

observatory variations, solar parameters that provide an averaged trend of quiet or storm time variations at any latitude or longitude. These have been compared with observatory data, providing robust estimates, in Realtime of magnetic disturbances. The longer, slower variations are obtained from monthly and annual means of observatory data. The trends seen in the data compiled over the last 150 years have been used to produce spherical harmonic representation of the Earth's magnetic field which is internally generated and its secular variation which are indicative of processes within the Earth's mantle and outer core. Definition of the main magnetic field and secular variation are currently supplemented by low-earth orbiting satellites (OERSTED, CHAMP, SWARM missions). This is one of the fastest growing areas of study.

Products and Uses of Observatory Data

Magnetic field values at different points on the Earth, their variation on different timescales are obtained. The Earth's magnetic field has been approximated as a dipole and more accurately expressed as a spherical harmonic series, based on time-averaged means of observatory data, by Gauss, demonstrating that 95% of the field intensity is derived from inside the Earth and 5% due to external currents in the atmosphere (now known as magnetosphere). From variations of the magnetic field at regularly sampled intervals, much information can be extracted. The time averaged values over months and years provide a data set approximating the potential field of the internally generated magnetic field. These values define the shape of the Earth's magnetic potential field (Fig. 4). This is termed the International Geomagnetic Reference Field, for a stated epoch (instant in time). Other data sets from magnetic surveys and satellites are added to refine the IGRF.

Daily variation at each observatory has contributed to the definition of solar-induced daily ionospheric currents (Sq). Variation with latitude and season has also been defined (Fig. 5). Monthly, seasonal, and annual variations are largely controlled by radiation (F10.7) from the sun. The effects of solar radiation on the ionosphere drive electric current loops in the ionosphere (height ~100 km). Study of these regular variations from both observatory data and in recent decades, from satellite data, has resulted in better models of the current loops and their variability. In addition, solar induced disturbances affect the earth's magnetic field.

Study and classification of magnetic disturbances, the influence of sunspot activity, and a theory explaining these phenomena, are evolved from a study of observatory data, during 1920–1940. This theory has since been corroborated from a direct observation of corpuscular radiation streams from the Sun and magnetospheric currents, by satellites. Each day's variations are analyzed and classified from quiet to disturbed, as a measure of magnetic activity in the earth's

Magnetic Methods, Surface, Fig. 4 Spatial variation of the Earth Magnetic field scalar (F), approximating a dipole field, over the Earth (www.geomag.bgs.ac.uk)

magnetosphere, in a manner that eliminates geographic difference. Geomagnetic indices were formulated as a composite of reported variations from observatories at different locations. These indices and several new ones continue to be reported and are updated, revised in accordance with discussion and resolutions passed by IAGA.

Observatory data are useful in determining rapid, medium term as well as slow variations in Earth's magnetic field. Each range of variations, studied for specific signals, contributes to the understanding of different processes (Fig. 6). Some of the phenomena being currently studied are:

- (i) Secular variation of the magnetic field at different places on the Earth. It is then expressed in spherical harmonic coefficients and included in the IGRF by adding time derivatives of coefficients. Variation in monthly and annual means, define the secular, slow change of the Earth's internal magnetic field. This has been mapped going back to about 300 years. The pattern of secular variation places constraints on the theory of generation of the Earth's magnetic field and maps fluid flow in the outer core. It is also the only means of studying electromagnetic and thermal properties of the Earth's outer core (depth: 3000 km). Knowledge of these variations is important in theoretical modeling of the geomagnetic dynamo. It is the only means of studying the motions

of the electrically conducting fluid in the Earth's outer core, where the main geomagnetic field is generated. These data are also widely used to calculate time-varying core field models, often in combination with satellite magnetic data or historical data.

- (ii) The regular variations of the magnetic field are related to rotation and/or orbital movements of the Earth, Sun, and Moon. The most prominent is the diurnal variation or solar daily variation, having amplitudes of the order of 10–100 nT (nanotesla). Solar radiation ionizes the higher atmosphere during the daylight hours, and the gravitational forces of the Sun and the Moon force the ionospheric layers in a tidal motion. So, the ionized gas in the ionosphere moves in the magnetic field of the Earth, creating electric currents which are seen as daily variations in magnetic recordings. There are two well-known periodic variations, the solar daily variation and the lunar daily variation. Studies of such variations at observatories around the world have resulted in models of Sq variations that incorporate ionospheric, atmospheric, and inter planetary effects. It is now possible to separate these effects, using averaged models.
- (iii) A global network is essential in monitoring the pattern of geomagnetic storms, local disturbances, mapping of currents generated in the magnetosphere, and thereby, inferences about presence of charged particles, models

(1996)) (www.wessexarch.co.uk marine survey, www.geologyscience.com magnetic survey)

Magnetic Methods, Surface, Fig. 6 A illustration of the wide spectrum geomagnetic variations (~ 1 s to 1 year) – (Serson 1983)

of magnetic field lines. These networks complement the intensive studies of satellite-borne magnetic data of the past two decades and with the ongoing SWARM mission

(iv) Induced currents in the crust and mantle are caused by external variations of the earth's magnetic field. For each periodic and episodic event described above, a corresponding current is induced in the finitely conducting layers of the Earth. An estimation of these currents provide a measure of the electrical conductivity distribution within the Earth's crust and mantle. This has been applied as a tool to study the Earth's interior and a large volume of electromagnetic variation data has been collected solely to this purpose. In the past decade, induced signals from satellite magnetic data have been used to model electrical conductivity distribution, over continents and oceans.

- (v) Ground observation networks provide calibration and control of magnetic survey satellites and complement detailed ground surveys of the magnetic field.
- (vi) Magnetic pulsations: 10 Hz – 600 s – are small amplitude variations generated at the boundary between magnetosphere and solar wind, under various dynamic conditions and transmitted through the magnetosphere and ionosphere and carry signatures of the properties of these regions as well.

Land and Marine Surveys

Principles of Survey Measurements

The measurement of spatial variation of magnetic field depends on determining the value at a spot, obtaining the position, time of measurement, and eliminating temporal variation, during the period of the survey, at each location. For this data have to be reduced to a time epoch in contrast to observatory measurements, which provide time variations at a fixed point. The objectives of a survey govern the use of specific magnetic instruments, surveying parameters (for example, observation elevation and data spacing), and the coordinate system used for the analysis of the data. For geological interpretation either total field scalar or vector measurements are suitable. But mapping of internally induced currents, in the crust – for tectonic studies, or in the mantle and outer core – for studies of the deep interior, require vector measurements. Instruments used vary from torsion magnetometer, fluxgate, proton precession, SQUID, etc. The precision of most modern instruments is between 0.1 and 1 nT. The residual, after removing temporal variation, is the variation in potential caused by deflection of field lines, through a volume of subsurface, that has non-uniform magnetic properties

Land Surveys

Magnetic surveys on land are conducted to find changes in physical properties of rocks in the subsurface (magnetic susceptibility). Local variations in the Earth's magnetic field are most often caused by ferromagnetic objects or other magnetic objects located in the vicinity of the studied area. Through measuring and recording of this variation, it is possible to detect objects submerged beneath the water (and sediments). An accurate map of the object's position can be created by recording the sensor's position along with the magnetic variation.

Vector or scalar field values are recorded, with precise location (GPS or surveying tools) and time. Time stamping of the data is critical, as the diurnal variations (quiet) as well as disturbances (storms) of the Earth's magnetic field are recorded at a base station in the survey area and eliminated

from the measurements over the survey area. The data is reduced to a time epoch, removing these external variations. IGRF values for that region are also be deducted. These corrections are made to eliminate temporal variations that are described above, from the data. Contributions of the Earth's main field at any particular location are removed from either vector or scalar measurements. Residual values obtained from the survey indicate changes in magnetic susceptibility in the subsurface, from which we infer, that there are changes in composition (Fig. 7a). This information is used to interpret the survey findings for a range of applications. Developments in Unmanned Aerial Vehicles (UAV) technology has made them suitable for geophysical surveys. Concurrently, magnetometers have also been adapted for this use, made robust and lightweight. The successful use of UAV-based surveys has increased the scope and capability of magnetic surveys over rough, forested and inaccessible terrains.

Typical applications are found in archeology, engineering studies, search and recovery of buried objects, mineral exploration, and geological structure mapping. The most significant change in magnetic properties occurs at Curie point, the depth varies considerably in different tectonic settings. Therefore, large-scale magnetic surveys provide significant inputs to deep crustal studies. Magnetic surveys are a viable method to obtain information regarding the crystalline basement over areas of sedimentary cover. The method has also been used to provide information on upper crustal structure and thermal state, along major geotranssects. Mapping of spatial magnetic variation provides information about the thickness of the basement rock beneath sedimentary basins/supracrustal rocks and thermal state of the crust of that region. For these surveys, satellite magnetic data has also been effectively used.

Marine Magnetic Surveys

Marine magnetometry surveys are carried out using a magnetometer specially modified for marine operations (Fig. 7b). The magnetometer is installed in a water-tight tow-fish, which is towed behind the vessel using a tow cable. The sensor used most often is a quantum magnetometer (proton precession or Overhauser). Magnetometers are somewhat more difficult to use than SONAR; however, they do provide accurate and reliable data. Since magnetometers do not directly measure the physical properties of the areas or objects of interest, the output signals of these sensors require some signal processing for translation into usable data. Methods of marine magnetic surveys are more elaborate, since instruments have to be towed behind a vessel and data collection is challenging. However, principles of analysis are similar. Similar corrections to marine survey data are applied to eliminate temporal variation and the contribution of the main magnetic field. However, with marine surveys, location of the towed magnetometer is also a critical factor. The speed of towing, movement of the magnetometer due to ocean swell, pitch, and roll

Magnetic Methods, Surface,

Fig. 7 (a) Sketch of land survey https://link.springer.com/referenceworkentry/10.1007/978-3-319-73568-9_8. (b) Schematic of a marine survey <http://ets.wessexarch.co.uk/recs/how-we-study-the-seafloor/geophysical-survey/04-magsurvey/>

reduce the accuracy of measurements. For measurements made in optimal sea conditions, time, trace, and main field corrections are adequate.

Magnetic surveys have a very diverse range of applications, including locating objects such as submarines, sunken ships, hazards for tunnel boring machines, hazards in coal mines, unexploded ordnance, toxic waste drums, as well as a wide range of mineral deposits and geological structures. Marine magnetic methods also map the variation in thickness of the oceanic crust – which consists of uniform magnetic material (basalt). Significant variations in marine magnetic measurements have been attributed to pulses of ocean-floor formation. These pulses belonging to different epochs have been identified by adjacent stripes of differing magnetization, of the ocean floor – a significant discovery of the phenomenon of “sea-floor spreading.”

Instrumentation Technologies

The principles of magnetometers are:

- (i) Torsion magnetometers: These measure the opposing force to the magnetic field – as in torsion fiber suspended magnetometers and deflection measurements. This was the oldest and mostly accepted method for nearly 200 years. Examples: Quartz horizontal magnetometer (QHM), Balance magnetometer Zero (BMZ), Kew Magnetometer, La Cour/Eschenhagen variometers and others.
- (ii) Flux measurement: It amplifies and measures in a ferrite sensor, with appropriate hysteresis – fluxgate magnetometers. Accuracy of fluxgate magnetometers can be adapted to different ranges of measurement. When

mounted in triaxial mode, they are given reliable values of the field. The Magnetometers are sensitive to temperature variation and internal noise, but these have been minimized by improved design. They are suitable for observatories, satellite, and unmanned vector measurements.

- (iii) **Magnetic Theodolite:** Estimating opposing force to the magnetic field as applied to a sensor of finite magnetic moment – using an oscillating magnet and theodolite, an old, classical method for absolute values – several instruments are still in use as secondary standards. A modern version of this is the Declination Inclination magnetometer. Thus, uses a singly fluxgate counted on a theodolite. This is adjusted to a null position to find the inclination of the magnetic field. In conjunction with total field measurement, this would result in vector components. The theodolite also gives azimuth and declination measurements. Since it is a null observation, accuracy is good. This has been adopted as standard for modern magnetic observatories and is increasingly used for surveys also.
- (iv) **Precession:** Based on the frequency of precession of hydrogen atoms (protons) after a strong external field is applied. Precession frequency is proportional to the ambient field. This is the most stable accurate method at present. Counting of frequency is very accurate with improved digital time stamping. The proton precession magnetometer measures only the scalar of total field intensity. An improvement of the same principle is the Overhauser magnetometer, which stimulates precession almost continuously and thereby produces a steady signal that is a measure of ambient field. This magnetometer is now chosen for most remote, continuous, and surveying operations.
- (v) **Optically pumped magnetometers:** The principle is of optical excitation of cesium (or other) gas, with a focused beam of coherent light. Zeeman splitting effect produces splitting of the lines emitted by the sample gas. The frequency of split is proportional to the ambient magnetic field.
- (vi) **Induction coil magnetometers:** This operates on the simple principle of measuring the output of a coil of many windings around a ferrite core. The signal is proportional to the derivative of the magnetic field. The induction coil has good response of a wide frequency range of measurement. This is used for rapid variation, e.g., pulsations, Magnetotellurics, etc.
- (vii) A recent development is the use of unmanned aerial vehicles (UAV), fitted with magnetometers. The magnetometers used are fluxgate, as well as quantum magnetometers and optically pumped magnetometers.

Summary

The shape, strength, and variations of the Earth's magnetic field have been studied over 500 years. Starting from measurements, repeated in time, at different places on earth, a model of the Earth's magnetic field in space and time has been built up. Magnetic observatories are places where long-time series of accurate measurements of the magnetic field are made, analyzed, and disseminated to institutions and persons seeking this information. Variations in different period ranges provide information about diverse processes, affecting the magnetic field. Short period variations (~min, hr) are indicative of disturbances in the magnetosphere caused by the Sun's corpuscular streams and magnetic fields, medium-term variations (~day, year) describe effects of the sun's radiation, and long-term variations (~year, decade, century) provide insights into the nature of the Earth's internal magnetic field, its origin, and modification in the Earth's outer core (secular variation). Closely spaced measurements on the Earth's surface are used in studies for resource exploration, tectonics, and mapping the formation of the oceanic crust.

The form of the Earth's magnetic field is redefined every 5 years, collating all available measurements as the IGRF. This also provides estimates of secular variation. Progress in satellite-based magnetic measurements (both vector and scalar) since 1999 have improved accuracy and precision of modelling spatial and temporal variations of the Earth's magnetic field. This has resulted in increasingly accurate models of processes on the Sun, in space, and on and within the Earth.

Definition

The geomagnetic field has a complex pattern, both in shape and strength, and changes continuously over time. Mathematical models need to be computed to describe the strength and direction at any point on or above the Earth's surface.

Introduction

When either a ground observatory or a satellite takes a geomagnetic field measurement, it represents the superposition of

many sources. The greatest contribution is generated by the dynamo action within the fluid, iron-rich core of the Earth, known as the core field. Although depending upon the altitude and location of the measurement, the data may have sizeable contributions from the static lithospheric field being generated largely from rocks and remanent magnetism within the Earth's crust. Internal in origin are also small magnetic signals produced by the electrical currents associated to the flow in oceans. On the other side, the external field sources originate in the ionosphere and magnetosphere. These sources include the daily solar quiet variations, the ring current variations, and many other current systems (e.g., the field-aligned currents and the auroral and equatorial electrojets). We also note that currents are induced in the Earth from these external fields. Sporadic magnetic storms and pulses, which have short-term effects, also play a role in the measured magnetic field values.

The knowledge of the Earth's magnetic field relies on various data sources, ranging from rock magnetization measurements to direct magnetic field measurements, from historic magnetic measurements to recent high-quality data provided by magnetic observatories and the magnetic satellites as MAGSAT, Ørsted, CHAMP, SAC-C, and recent Swarm constellation (Manda and Purucker 2018). A combination of ground and continuous satellite measurements allows the core magnetic field and its time variation to be described with a very high resolution in space and in time, on a global scale (e.g., Finlay et al. 2017). On the other hand, recent dynamo simulations have also contributed to the understanding of the core field geometry and its dynamics, and temporal changes: some are dipole dominated, and can show polarity reversals (Jones 2015), others more towards Earth-like, do not show reversals anymore (Schaeffer et al. 2017).

The geomagnetic field changes in space and time, therefore magnetic observations must continually be acquired, on ground and near-Earth's space. The magnetic observations are performed in different ways and using various platforms. Geomagnetic observatories have provided the highest quality data, however with a very uneven spatial distribution. To increase the spatial density regionally, repeat station surveys have been conducted by many teams, but at a national scale only. Over the last decades, magnetic satellites have offered a uniform, global coverage, but face problems of attitude control and ambient current in the surrounding plasma.

This very brief description of the sources contributing into magnetic measurements and of the variety of magnetic observations shows how challenging is to obtain a reliable mathematical description of the magnetic field to be used in the modeling process. New mathematical tools need to be developed to accurately describe magnetic data. Depending on the available data and the base functions, these models are global or regional, static or time dependent. The mathematical

description of the different kinds of field models, their physical backgrounds, and applicability are vast topics subjects, and cannot be covered in detail here. Therefore, the main aim of this contribution is to give the reader a basic support and information for more detailed references.

Global Field Modeling

Spatial and Temporal Description

The geomagnetic field is global in nature, so the most obvious approach is to describe it on the whole Earth's surface. The magnetic field, following the Maxwell equations, is so it can be written as:

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad (1)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (2)$$

where $\mathbf{H}$ is the magnetic field, $\mathbf{B}$ is the magnetic induction, $\mathbf{J}$ is the current density, and $\partial \mathbf{D} / \partial t$ is the electric displacement current density. In a region without magnetic field sources, for example, from the Earth's surface up to about 50 km, it is reasonable to assume that $\mathbf{J} = 0$ and $\partial \mathbf{D} / \partial t = 0$, so $\nabla \times \mathbf{H} = 0$, meaning that the vector field is conservative in the region of interest, and the magnetic field $\mathbf{H}$ can be expressed as $\mathbf{H} = -\nabla V$, where V is a scalar potential. Because $\mathbf{B} = \mu_0 \mathbf{H}$ above the Earth's surface (where $\mu_0 = 4\pi \times 10^{-7} \text{ Hm}^{-1}$), it follows that for the geomagnetic field $\nabla \cdot \mathbf{H} = 0$ and that V has to satisfy Laplace's equation:

$$\nabla^2 V(\theta, \phi, r) = 0. \quad (3)$$

Here, we underline that in geomagnetism the magnetic induction $\mathbf{B}$ is traditionally called "magnetic field," and we use this notation in the following. In spherical coordinates (θ, ϕ, r) , which are the geocentric colatitude, longitude, and radial distance, Laplace's equation takes the following form:

$$\begin{aligned} \frac{1}{r} \frac{\partial^2}{\partial r^2} (rV) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial V}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 V}{\partial \phi^2} \\ = 0. \end{aligned} \quad (4)$$

Equation 4 solutions are products of three expressions (the first is to be only a function of r , the second only a function of θ , and the third only a function of ϕ) and can be solved by separation of variables. A completely general solution is provided by spherical harmonics, and can be written in such a form to express two important contributions in the potential field: a part V^{int} describing the internal (core and lithospheric) sources, and a part, V^{ext} , describing the external (mainly magnetospheric) sources:

$$\begin{aligned} V &= V^{\text{int}} + V^{\text{ext}} \\ &= a \sum_{n=1}^{N_{\text{int}}} \sum_{m=0}^n \\ &\quad \times (g_n^m \cos m\phi + h_n^m \sin m\phi) \left(\frac{a}{r} \right)^{n+1} P_n^m(\cos \theta) \\ &\quad + a \sum_{n=1}^{N_{\text{ext}}} \sum_{m=0}^n \\ &\quad \times (q_n^m \cos m\phi + s_n^m \sin m\phi) \left(\frac{r}{a} \right)^n P_n^m(\cos \theta), \end{aligned} \quad (5)$$

where $a = 6371.2 \text{ km}$ is a reference radius, (θ, ϕ, r) are geocentric coordinates, P_n^m are the associated Schmidt-normalized Legendre functions, N_{int} is the maximum degree and order of the internal potential coefficients g_n^m, h_n^m , and N_{ext} is that of the external potential coefficients q_n^m, s_n^m .

Some of the base functions show special characteristics and are named individually:

- Zonal functions are characterized by $m = 0$ and oscillate only in the latitudinal direction
- Sectorial functions are defined by $n = m$ and oscillate only in the longitudinal direction
- Tesseral functions oscillate in both the longitudinal and latitudinal direction

The Gauss coefficients are used to define the magnetic field in terms of "sources." The first term, g_1^0 , is associated with the geocentric dipole oriented along the vertical axis, i.e., axis of the Earth's rotation, with dipole moment $g_1^0 4\pi a^3 / \mu_0$. The next two terms, g_1^1, h_1^1 , characterize the geocentric dipoles oriented along the two last orthogonal axis. The magnitude of the *geocentric dipole* is given by $M = (4\pi a^3 / \mu_0) \left((g_1^0)^2 + (g_1^1)^2 + (h_1^1)^2 \right)^{1/2}$, and it is tilted at roughly 11° from the rotation axis. The potential for a dipole falls off as r^{-2} , and the strength of the field components as r^{-3} . Similarly, for $n = 2$ the terms represent the *geocentric quadrupole* (potential falls off as r^{-3} and the strength as r^{-4}), for $n = 3$ the terms represent the *geocentric octopole* (potential falls off as r^{-4} and the strength as r^{-5}), and so forth. An accurate description of the internal field to high degrees and orders involves a weighting scheme of many parameters of this inverse problem and on the way to handle the ionospheric and magnetospheric signatures in spherical harmonics (e.g., Finlay et al. 2016; Finlay et al. 2017; Lesur et al. 2010; Sabaka et al. 2015).

The first three Gauss coefficients (g_0^1, g_1^1, h_1^1) represent the *dipole* field, while the remaining terms represent the *nondipole field*. The lowest degree terms correspond to the largest wavelength features of the field, and are dominated by zonal harmonics. The first Gauss coefficient

has a $\cos\theta$ dependence, so at distance r the “wavelength” of the associated magnetic feature is $2\pi r$. Generally speaking, the term g_n^m has a wavelength of $2\pi r/(n + \frac{1}{2})$ (Backus et al. 1996). To describe only the part of the geomagnetic field with sources beneath the Earth’s surface, only the part V^{int} of Eq. 5 is used. However, this first term of Eq. 5 describes both the core and lithospheric fields. The usual way to separate sources originating in the core from those originating in the lithosphere (Loves 1966) is by computing the mean square value of the field over the Earth’s surface produced by harmonics of a given n :

$$W_n = (n+1) \sum_m \left((g_n^m)^2 + (h_n^m)^2 \right). \quad (6)$$

Variation of W_n depends on the degree n , which is known as the power or Lowes–Mauersberger spectrum, and Fig. 1 shows its behavior. The steep part of the spectrum ($n \leq 13$) indicates the signature of the long wavelengths of the core field; the transition degrees ($n = 14-15$) can be attributed to the signals from both core and lithospheric sources, and the higher degrees ($n \geq 16$) are dominantly lithospheric in origin.

The above description in terms of spherical harmonics is used to characterize static or “snapshot” fields. Considering the definition of the magnetic field components X , Y , and Z (in the northward, eastward, and radially inwards directions) and the definition of the spherical polar coordinates (Merrill et al. 1996), it is apparent that $X = -B_\theta$, $Y = B_\phi$ and $Z = -B_r$. For a given epoch, the components of the geomagnetic field are obtained from the model

coefficients using the internal part of Eq. 5, as derivatives of potential.

$$\begin{aligned} B_\theta &= -\frac{1}{r} \frac{\partial}{\partial \theta} (V^{\text{int}}) \\ &= -\sum_{n=1}^{N_{\text{int}}} \sum_{m=0}^n (g_n^m \cos m\phi + h_n^m \sin m\phi) \left(\frac{a}{r}\right)^{n+2} \frac{\partial}{\partial \theta} P_n^m(\cos \theta) \end{aligned} \quad (7)$$

$$\begin{aligned} B_\phi &= -\frac{1}{r \sin \theta} \frac{\partial}{\partial \phi} (V^{\text{int}}) \\ &= \frac{1}{\sin \theta} \sum_{n=1}^{N_{\text{int}}} \sum_{m=0}^n m (g_n^m \sin m\phi - h_n^m \cos m\phi) \left(\frac{a}{r}\right)^{n+2} P_n^m(\cos \theta) \end{aligned} \quad (8)$$

$$\begin{aligned} B_r &= -\frac{\partial}{\partial r} (V^{\text{int}}) \\ &= \sum_{n=1}^{N_{\text{int}}} \sum_{m=0}^n (n+1) (g_n^m \cos m\phi + h_n^m \sin m\phi) \left(\frac{a}{r}\right)^{n+2} P_n^m(\cos \theta) \end{aligned} \quad (9)$$

Traditionally, the system of coordinates used in geomagnetism is the North, East, Center (sometimes denoted X , Y , Z).

Since the geomagnetic field changes in space and time, the Gauss coefficients are also time dependent. In order to model time variations of internal origin, the *secular variation*, about 1 year of continuous observations is needed. This variation is often assumed to be constant over short time scales, and can be introduced by adding a secular variation potential, V_{sv} , truncated to N_{sv}^{max} .

Magnetic Modeling, Theory, and Computation, Fig. 1 The power spectrum for an internal part of a magnetic field model: the steep part of the spectrum ($n \leq 13$) indicates the core field contribution, the transition degrees ($n = 14-15$) can be attributed to both core and lithospheric contributions, and the higher degrees ($n \geq 16$) describe the lithospheric contribution. Units are in nT^2

$$V_{sv} = a \sum_{n=1}^{N_{sv}^{max}} \left(\frac{a}{r} \right)^{n+1} \sum_{m=0}^n (t - T_0) \left(\dot{g}_n^m \cos(m\phi) + \dot{h}_n^m \sin(m\phi) \right) P_n^m(\cos(\theta)) \quad (10)$$

where $\dot{g}_n^m$ and $\dot{h}_n^m$ denote the time derivatives of the internal Gauss coefficients, T_0 the reference time (i.e., the epoch of the core field model), and t is the considered time. Recently, due to a few decades of high-resolution, high-precision satellite magnetic data, the secular acceleration can also be described, by coefficients $\ddot{g}_n^m$ and $\ddot{h}_n^m$, denoting the second time derivative of the Gauss coefficients.

The time dependence of the core field coefficients $\{g_n^m(t), h_n^m(t)\}$ up to a given degree n can also be described by temporally more complex functions, e.g., B-splines. Splines of order four result in a piecewise linear representation of $\partial_t^2 \mathbf{B}$, which is not favorable for studying sudden changes in the rate of core field changes (geomagnetic jerks). Higher-order splines result in a smoother representation of $\partial_t^2 \mathbf{B}$ and are therefore preferable. In order to be able to describe rapid field temporal variations of the core field, a 6-month knot separation is recommended.

Inverse Problem and Implementation

To obtain a geomagnetic model and thereafter the field component description, an inverse problem needs to be solved, for which the standard model estimation technique is summarized below.

The aim is to describe a given dataset in terms of a series of parameters. The data can be assembled in a data vector $\mathbf{d}$ of length N

$$\mathbf{d}^T = (\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_N). \quad (11)$$

The model is defined by a set of M parameters assembled in a model vector of length M

$$\mathbf{m}^T = (\mathbf{m}_1, \mathbf{m}_2, \dots, \mathbf{m}_M). \quad (12)$$

The basic assumption is that the data are related to the model parameters through a function $\mathbf{F}(\mathbf{m})$, leading to the relation:

$$\mathbf{d} = \mathbf{F}(\mathbf{m}), \quad (13)$$

which, for linear (or linearized) problems, reduces in a matrix form:

$$\mathbf{d} = \mathbf{A}\mathbf{m}. \quad (14)$$

where $\mathbf{A}$ is a $N \times M$ matrix of coefficients, independent of data values and model parameters. In the case of spherical

harmonics analysis, the data are often the three components of the magnetic field vector. The Gauss coefficients define the parameter vector $\mathbf{m}$. The $\mathbf{A}$ matrix elements contains M base functions evaluated at N data positions – i.e., spherical harmonics (or their gradients) and their radial dependence.

Generally, more data are available than parameters to be resolved, so $N \geq M$. In this case, the above equation cannot be satisfied for every data: the inverse problem is overdetermined and has no exact solution. Hence, the model parameters are sought such that the above equation is solved approximately. The least square method minimizes the sum of the squares of the errors in order to find a solution. The usual solution to this problem is given by:

$$\mathbf{m} = (\mathbf{A}^T \mathbf{W} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{W} \mathbf{d} \quad (15)$$

as long as the inverse matrix $\mathbf{G}^{-1} = (\mathbf{A}^T \mathbf{W} \mathbf{A})^{-1}$ exists. To define the weight matrix $\mathbf{W}$, we need to consider that magnetic data from different platforms, and at different times, can be affected by different error sources and these error sources can even be correlated. The covariance matrix $\mathbf{C}_d$ associated with these errors must be estimated, inverted, and then used as weight matrix, i.e., $\mathbf{W} = \mathbf{C}_d^{-1}$. For uncorrelated data, the covariance matrix is diagonal. In practice, this is rarely the case, but for computational simplicity diagonal covariance matrices are often used.

Inverse problems are sometimes ill-posed – i.e., some parameters or combination of parameters are not resolved by data. In that case the inverse of $\mathbf{G} = (\mathbf{A}^T \mathbf{W} \mathbf{A})$ does not exist, or is numerically difficult to estimate. It shows that small errors in data values can lead to considerable changes in the parameters. The error amplification must be controlled by appropriate measures in the solution process: inverse problems can be regularized by introducing regularization matrices in space and time. A solution in the least square sense writes now as:

$$\mathbf{m} = (\mathbf{A}^T \mathbf{W} \mathbf{A} + \lambda_t \Lambda_t + \lambda_s \Lambda_s)^{-1} \mathbf{A}^T \mathbf{W} \mathbf{d}. \quad (16)$$

It corresponds to a minimum of the functional as:

$$\Phi = (\mathbf{d} - \mathbf{A}\mathbf{m})^T \mathbf{W} (\mathbf{d} - \mathbf{A}\mathbf{m}) + \lambda_t \mathbf{m}^T \Lambda_t \mathbf{m} + \lambda_s \mathbf{m}^T \Lambda_s \mathbf{m} \quad (17)$$

The choice of λ_t and λ_s damping parameter values is difficult, and often a computationally intensive task. If criteria exist to determined these parameters, they are often unpractical to establish, and therefore the parameters choice often depends on the modeler skills, interests, and a priori knowledge on the solution. The same formalism is used to impose constraints on the model solution.

The models developed are more and more complex to satisfy the high quality of the recent satellite data due to the overall progress in data acquisition techniques and quality. This has led to the development of complex codes, over several years, that use up-to-date numerical techniques.

From a computational point of view, when large datasets are used, the most time-consuming step in building a model is to compute the matrix $\mathbf{G} = (\mathbf{A}^T \mathbf{W} \mathbf{A})$. Typically, a parallel computing environment is necessary to compute this matrix in a reasonable amount of time – e.g., less than a few days. Often, a re-weighted least square approach is needed to reach the best solution, requiring the evaluation of $\mathbf{G}$ numerous times. In comparison, inverting the matrix takes only few minutes for models with 10 to 20 thousands of parameters. Overall, several months are needed by a trained modeler to derived a robust model of the Earth's interior magnetic field.

Recent Developments in Magnetic Field Modeling

Although magnetic field models obtained through the inversion process described in the previous section provide an accurate view of the present main geomagnetic field, they still strongly rely on the modeler skills and choices. Further, as the combined datasets from different satellite missions accumulate, it becomes more and more difficult to handle the large amount of data and the complexity of the models required to fit them. As a consequence, new approaches are needed. These are typically iterative, handle a small amount of data at a time, and rely mostly on Kalman filters to build their temporal evolution. In their current implementation to geomagnetic field modeling these approaches do not introduce heavy computational costs, even for the most complex models. Of course such approaches are very close to data assimilation methods. They have been introduced in geomagnetism mainly to study the core dynamics from magnetic field models (Aubert 2015; Baerenzung et al. 2018; Barrois et al. 2017; Gillet et al. 2015).

These approaches require three steps: analysis, prediction, and smoothing. The analysis step is nothing else than a Bayesian-based modeling (e.g., Gillet et al. 2013; Holschneider et al. 2016; McLeod 1996) where Gaussian distributions are used to describe the model and data error distributions. Technically, this step shows strong similarities with what has been described in the previous section. It consists of correcting a known magnetic field model such that it fits a small set of data. It writes:

$$\mathbf{m} = \tilde{\mathbf{m}} + \left(\mathbf{A}^T \mathbf{C}_d^{-1} \mathbf{A} + \mathbf{C}_m^{-1} \right)^{-1} \mathbf{A}^T \mathbf{C}_d^{-1} (\mathbf{d} - \mathbf{A} \tilde{\mathbf{m}}) \quad (18)$$

where $\tilde{\mathbf{m}}$ is the known magnetic field – i.e., the prior. It can also be a null vector. $\mathbf{C}_m$ is its covariance matrix and $\mathbf{C}_d$ is, as before, the covariance matrix of the data errors. Outside the usual difficulty in estimating $\mathbf{C}_d$, this step also requires

knowing the matrix $\mathbf{C}_m$, and inverting it. In Holschneider et al. (2016) simple correlation structures, and associated correlation matrices, for all possible magnetic sources of internal and external origins are proposed. More sophisticated matrices can be derived from theoretical model of the sources – e.g., from numerical dynamo experiment (Aubert 2015). The posterior covariance matrix of the model $\mathbf{m}$ can be estimated using:

$$\mathbf{C}_m = \left(\mathbf{A}^T \mathbf{C}_d^{-1} \mathbf{A} + \mathbf{C}_m^{-1} \right)^{-1}. \quad (19)$$

We note that when working with satellite data, the process described above is often preferred to an approach using classic Kalman gain matrices, because the number of accumulated data after a few days easily exceed the dimension of the models.

The prediction step requires introducing a multivariate random variable $\mathbf{y}$ normally distributed with a mean $\bar{\mathbf{y}}$ and covariance matrix $\mathbf{C}_y$ – i. e. $\mathbf{y} \sim \mathcal{N}(\bar{\mathbf{y}}, \mathbf{C}_y)$. Assuming that there is a known magnetic field model $\mathbf{m}_k$ and its associated covariance matrix $\mathbf{C}_{m_k}$ at time t_k , then at time t_{k+1} a prediction of the model $\tilde{\mathbf{m}}_{k+1}$ and its covariance matrix $\mathbf{C}_{\tilde{m}_{k+1}}$ are obtained through:

$$\begin{aligned} \tilde{\mathbf{m}}_{k+1} &= \mathbf{P}_k \mathbf{m}_k + \bar{\mathbf{y}} \\ \mathbf{C}_{\tilde{m}_{k+1}} &= \mathbf{P}_k \mathbf{C}_{m_k} \mathbf{P}_k^T + \mathbf{C}_y. \end{aligned} \quad (20)$$

The operator $\mathbf{P}_k$ predicts the evolution of the magnetic field model (the description is limited here to a simple linear case). This operator generally depends on the time step $t_{k+1} - t_k$ and on the characteristic time scales of the model. It can be as simple as a scaled identity matrix. The multivariate random variable $\mathbf{y}$ describes the error associated with the prediction process. So far, in most applications of this method to geomagnetic field modeling it has zero mean – i.e., $\bar{\mathbf{y}} = 0$. As $\mathbf{P}_k$, the covariance matrix $\mathbf{C}_y$ necessarily depends on the time step $t_{k+1} - t_k$ and characteristic time scales of the model, but it must also describe the correlation structure of the model. Examples of prediction process, although not necessarily linear as presented here, can be found, e.g., in Baerenzung et al. (2018), Beggan and Whaler (2009), Fournier et al. (2015), and Gillet et al. (2015).

A succession of analysis and prediction steps allows to build a sequence of magnetic field models for the required time span. The only difficulty of this sequential approach is that at a given time the model is built without knowing how the observed geomagnetic field will evolve in the future. This limitation is resolved by using the smoothing step. There are several ways to handle the smoothing and we present here a simple method that works for linear Gaussian problems (Anderson and Moore 1979). Let assume a sequence of models $\mathbf{m}_k$ and their associated covariance matrices $\mathbf{C}_{m_k}$, for

$k = 1, \dots, N$ with $t_{k+1} = t_k + \delta k$. The sequence of smoothed models $\mathbf{m}_k^s$ is derived iteratively, backward in time, starting from $\mathbf{m}_N^s = \mathbf{m}_N$. We introduce first the matrix $\mathbf{G}_k$ defined by

$$\mathbf{G}_k = \mathbf{C}_{m_k} \mathbf{P}_k' (\mathbf{P}_k \mathbf{C}_{m_k} \mathbf{P}_k' + \mathbf{C}_y)^{-1}. \quad (21)$$

The sequence of models is built with

$$\begin{aligned} \mathbf{m}_k^s &= \mathbf{m}_k + \mathbf{G}_k (\mathbf{m}_{k+1}^s - \mathbf{P}_k \mathbf{m}_k) \\ \mathbf{C}_{m_k^s} &= \mathbf{C}_{m_k} - \mathbf{G}_k (\mathbf{P}_k \mathbf{C}_{m_k} \mathbf{P}_k' + \mathbf{C}_y - \mathbf{C}_{m_{k+1}^s}) \mathbf{G}_k'. \end{aligned} \quad (22)$$

To our knowledge, currently, the only magnetic field model released using specifically the technique described here is (Lesur et al. 2017), although no smoothing was applied. Several other authors have shown progress in this direction. There is no doubt that such models will be released soon, in particular for the publication of the next version of the IGRF that is due in 2020. As a new release, the model used in this study to map features of the core field and its variations at the Earth's surface and at the core–mantle boundary (CMB) is the one proposed as candidate for IGRF-13 (Ropp et al. 2020). We note that (Barrois et al. 2018) released a model established using a very similar technique, where the covariances are estimated through ensemble methods. The algorithm presented in their paper does not include a smoothing step. The setup is generally rather complex as the geomagnetic main field and the flow are co-estimated at the top of the liquid outer core.

Maps of the core field and its secular variations, at the Earth's surface are plotted in Figs. 2 and 3.

Regional Field Modeling

To describe the magnetic field at regional scales, different methods have been proposed during the last decades, starting with the spherical cap harmonic analysis proposed by Haines (1985) and the related translated origin spherical cap harmonic analysis (Korte and Holme 2003). The spherical cap harmonic analysis permits the use of data from only a region of the Earth while satisfying the constraints of potential field theory. Indeed, the region to be studied has to be defined by a spherical cap and satisfies the zero curl and divergence conditions. The method is claimed to be valid over any spherical cap at any altitude above the Earth's surface. On the basis of these assertions, the method has been widely used for constructing regional magnetic maps. However, a few issues are to be taken into account when using this approach. The main one appears as a failure to correctly model the radial dependence (i.e., that the models cannot be upward and downward continued and data acquired at different altitudes

Magnetic Modeling, Theory, and Computation, Fig. 2 Maps of the core field components (units in nT): northward component (top), eastward component (middle), and radially inwards direction (bottom) at the Earth's surface in 2019. Mollweide projection is used

Magnetic Modeling, Theory, and Computation, Fig. 3 Maps of the core field secular variation (units in nT year^{-1}): northward component (top), eastward component (middle), and radially inwards direction (bottom) at the Earth's surface in 2019. Mollweide projection is used

cannot be simultaneously inverted). In order to solve this difficulty, (Thebault et al. 2004) have reposed this method as a boundary value problem within a cone extending above the reference surface, thereby allowing satellite data to be downward continued to the Earth's surface.

Some different basic functions, such as harmonic splines (Shure et al. 1982) or with more local support, wavelet-like functions (Holschneider et al. 2003; Lesur 2006) are also suited to describe datasets with variable resolution over the area of interest. Only these two approaches are summarized in the following.

We also note that maps of magnetic field at regional scales can be used together with gravity field anomalies to get information about physical properties of the Earth's crust and upper mantle (see also next section), helpful in understanding geological settings and tectonic structures. Depending on data availability, whether from the ground, airborne, or from satellites, potential field anomaly maps contain information on different ranges of spatial wavelengths, roughly corresponding to sources at different depths. One example is provided by (Korte and Mandea 2016).

Harmonic Splines

A detailed description of harmonic splines can be found in Shure et al. (1982), and a recent application for the Southern African continent magnetic data in Nahayo et al. (2018). The main interests of this representation is that it offers a smoothness property to the derived field model.

The method considers the magnetic field as expressed as the gradient of a scalar potential, as shown in the previous section. Using the spherical harmonics Y_n^m of degree n and order m , the internal part of the global magnetic field can be written as

$$B = -\nabla a \sum_{n,m}^N g_n^m \left(\frac{a}{r}\right)^{n+1} Y_n^m(\theta, \phi) \quad (23)$$

with the same notations as in 5. An alternative representation of the field is given by:

$$B(\theta, \phi, r) = -\sum_i \alpha_i \nabla F_i^{Nr}(\theta, \phi, r) \quad (24)$$

$$F_i^{Nr} = a \sum_{n,m}^N f_n(n+1) \left(\frac{a}{r}\right)^{n+1} \left(\frac{a}{r_i}\right)^{n+2} Y_n^m(\theta_i, \phi_i) Y_n^m(\theta, \phi) \quad (25)$$

$$f_n = \frac{2n+1}{4\pi n^2(n+1)^4} \quad (26)$$

with this choice of parameter f_n values, the modeled magnetic field minimizes the quantity

$$\int_{\Omega} |\nabla_h^2 B_r|^2 d\omega. \quad (27)$$

In the framework of regional analysis, in order to insure a fit to the data, it is necessary to introduce for the representation of the magnetic field two further sets of functions similar to 25. This gives:

$$B(\theta, \phi, r) = -\nabla \left(\sum_i \alpha_i^r F_i^{Nr}(\theta, \phi, r) + \sum_i \alpha_i^\theta F_i^{N\theta}(\theta, \phi, r) + \sum_i \alpha_i^\phi F_i^{N\phi}(\theta, \phi, r) \right) \\ F_i^{N\theta} = a \sum_{n,m} f_n \left(\frac{a}{r} \right)^{n+1} \left(\frac{a}{r_i} \right)^{n+2} \frac{\partial}{\partial \theta} Y_n^m(\theta_i, \phi_i) Y_n^m(\theta, \phi) \quad (28)$$

$$F_i^{N\phi} = a \sum_{n,m} f_n \left(\frac{a}{r} \right)^{n+1} \left(\frac{a}{r_i} \right)^{n+2} \frac{1}{\sin \theta} \\ \times \frac{\partial}{\partial \phi} Y_n^m(\theta_i, \phi_i) Y_n^m(\theta, \phi). \quad (29)$$

As a recent application of this approach we note the study made by Nahayo et al. (2018). The authors investigated the Southern African continent region where the geomagnetic field is weaker and changes more rapidly compared to other regions of the Earth. The CHAMP satellite data and relatively dense spaced ground-based data obtained from the repeat stations network together with permanent geomagnetic observatories are used. For the period 2005–2010 these datasets are combined in a new regional, harmonic spline-based, core field model, used to investigate the evolution of the South Atlantic anomaly in this region.

Wavelet Analysis

The wavelet frames and the work by Chambodut et al. (2005) and Holschneider et al. (2003) have pioneered the use of wavelet frames for constructing regional potential field models. In particular on the sphere, the used functions should satisfy the following properties: (i) harmonic prolongation must be easily computable; (ii) function itself has to be numerically easy to compute; and (iii) functions must be localized on the sphere.

The indicated requirements lead to constructions based on the Poisson kernel of spherical functions. A Poisson wavelet at a given point on the unit sphere is expressed as:

$$\psi_a^k(x) = N_a^k \sum_n (an)^k e^{-an} Q_n(\cos \mu) \quad (30)$$

where N_a^k is a normalization constant and μ is the angle between the wavelet position and the data point position. The Q_n function is defined by

$$Q_n(\cos \mu) = (2n+1)P_n(\cos \mu), \quad (31)$$

which can be expressed easily in terms of products of spherical harmonics.

The wavelet is defined by three parameters: scale a , position, and order k . The scale a is a measure of the wavelength of the wavelet without dimension, and order k characterizes the global shape of the wavelets (number of oscillations). The wavelets on the sphere may also be considered as a restriction on the sphere of a function that is harmonic outside and that has singularities inside it. The main characteristic of a wavelet is its relatively well-localized amplitude on the sphere, hence well adapted to regional modeling, while spanning a relatively limited range of wavelengths.

One application of this approach concerns the separation of the internal and external contributions in vector magnetic data, as those provided by CHAMP and Swarm satellites. A pioneering work in this domain is found in Mayer and Maier (2006) where it is shown that wavelets technique is especially applicable for modeling and analyzing small spatial effects like the geomagnetic field originating in the lithosphere.

Interpretation

The geomagnetic field models, at global and regional scales, play an important role in our modern world. The Earth's magnetic field can be used as a tool in screening our planet, and for understanding its deep interior processes. Moreover, these models can be used for some specific applications, as in navigation, to protect the technological systems affected by large geomagnetically induced currents, in satellite operations, or exploration geophysics. From this list, which is far for being complete, three case studies are given here, one linked to interpretation of the magnetic field and its secular variation at the core–mantle boundary, and two linked to the lithospheric field.

Core Magnetic Field at Core–Mantle Boundary

A better description of the short temporal and spatial variability of the internal field would provide insights on the processes generating the internal field and the dynamical regime in Earth's liquid outer core. The core field changes on temporal scales from months to millennia, even longer. For temporal scales covering the satellite era the lithospheric field is

considered static. Indeed, recently, (Sebera et al. 2019) shows that the effect of the time-varying lithospheric field over 17 years (since the launch of CHAMP) is at the edge of the detectability reaching peak-to-peak values about 0.5 nT depending on the area and the altitude.

As described above, models of the magnetic field generated inside the Earth are dominated for the long wavelengths by the core field, and for the shorter wavelengths by the lithospheric field. The longest wavelengths of these models – roughly up to spherical harmonics of degree 14 – can therefore be used to try to understand the generation process of the core field. Results from seismological observations have shown that the core can be separated in two regions; a solid inner core of radius estimated at 1220 km and a liquid outer core in the spherical shell extending up to 3485 km. This liquid outer core is very conductive and made mainly of liquid iron in convection, which in presence of a magnetic field, can regenerate this field, balancing its natural decay due to ohmic dissipation. This process is known as the geodynamo. The best way to retrieve information about the dynamics of the core and the fluid motions at the top of the core is through magnetic data acquired at, or above, the Earth's surface. The magnetic field models are therefore downward continued, through the mantle, to the core–mantle boundary (CMB) assuming that the mantle is an insulator. In principle, only the radial component of the magnetic field can be derived just below the CMB, because of the unknown jump of the electrical conductivity across the CMB, associated with a discontinuity of the magnetic field components tangential to the boundary.

An image of this vertical down component of the core magnetic field just below the CMB is shown in Fig. 4, together with its expected time derivative. These images correspond to a magnetic field model truncated to spherical harmonic degree 13. Contributions from shorter wavelengths may considerably modify these images, but these contributions are unknown, being hidden by the lithospheric field or the noise, at the Earth's surface. However, considerable information can be readily extracted from these maps. One can see that the core field has a much more complex structure at the CMB than on the Earth's surface (Fig. 2). In particular, the presence in the southern hemisphere of a large patch of reverse orientation of the magnetic field – the field there is oriented towards the core interior, whereas in a simple dipole approximation one would expect the field to be oriented outward. This patch and its evolution has attracted scientist's attention over the last decades because it is associated with the weakness of the Earth's field in the South-Atlantic region, it contributes significantly in the decrease in the strength of the Earth's dipole field component, and it has sometimes been thought as an early stage of a reversal process (Hulot et al. 2002; Olsen and Manda 2008). Regarding the secular variation, it is obviously concentrated at mid latitudes and high

latitudes of the north hemisphere. It is extremely weak under the Pacific ocean and southern part of the south hemisphere.

The combination of the Maxwell equations leads to the so-called induction equation. Under the frozen-flux approximation, that neglects the diffusion in front of induction, the radial component of this equation writes:

$$\frac{\partial}{\partial t} B_r = -\nabla_h \cdot (B_r U_h) \quad (32)$$

where B_r is the radial component of the magnetic field, U_h is the horizontal component of the flow under the CMB, and ∇_h is the tangential gradient on the sphere. This equation simply shows that the main source of secular variation is the advection of the field lines by the flow. Since radial component of both the field and its secular variation can be estimated at the CMB, this equation provides a way to get some information on the flow at the top of the liquid outer core, for large spatial wavelength and relatively short time scales. By combining this with constraints derived from the equations of fluid dynamics and/or magnetohydrodynamics, it is possible to derive physical properties of the outer core and shed light on unexplained phenomenon as geomagnetic jerks, (Manda et al. 2010) or contributions to the variation of the length of the day.

Lithospheric Magnetic Field over the Arctic and African Regions

The magnetic signature of the lithosphere is related to all the processes that affected and shaped the figure of our planet. To first order, the remanent magnetic contributions are canceled out at large wavelength and the induced part dominates above continental domains. The exact contribution of the remanent magnetization is actually difficult to estimate, unless the physical properties of the magnetic sources are known through rock sampling and analysis. It is possible to estimate what is their relative contribution by using global forward approaches, mostly relying on the distribution of the vertically integrated magnetization. A simple estimate is based on the lateral magnetization contrast associated with the boundary between oceanic and continental domains. Indeed, the abrupt boundaries between the thin oceanic crust and the thicker continental crust translate into a large-scale magnetic signal which is present above the continental margins, and also above continental and oceanic basins. This does not suffice to explain all the observed magnetic anomalies. Those interested in the crustal magnetic field are referred to some reviews, like Langlais et al. 2009.

Generally speaking, the lithospheric magnetic field reflects the magnetization associated with minerals cooling down below their Curie temperature in the presence of a magnetic field. Above the Curie temperature, the magnetization vanishes, and minerals exhibit then paramagnetic susceptibility,

Magnetic Modeling, Theory, and Computation, Fig. 4 Map of the core field vertical down component (units in nT, top) and its secular variation (units in nT year⁻¹, bottom) at the core–mantle boundary, for 2019. Mollweide projection is used

with little effect compared to magnetization. Therefore, rocks are essentially nonmagnetic at temperatures greater than the Curie temperature characterizing their main magnetic minerals constituents. Taking into account a normal geothermal gradient, sources of the measured magnetic signal are then restricted to some maximum 30–40 km depth, excepting the old cratonic areas where the Curie depth – depth at which the temperature reach the Curie temperature – may be deeper. Different methods are proposed to estimating the depth to the

bottom of magnetic sources from magnetic data and based on the spectral analysis of magnetic anomalies (Blakely 1995; Bouligand et al. 2009; Spector and Grant 1970). A recent study (Audet and Gosselin 2019) concluded that the estimated Curie depth values are rather unreliable unless prior information on one or all model parameters is included in calculations. Curie depth estimates where the lithosphere is thinner or the magnetization is likely to be uniform are more reliable than in regions with thick and heterogeneous lithosphere.

Satellite data is of particular importance for unraveling the origin and structure of large lithospheric domains, which are difficult to access and map, like the polar regions or the African continent.

The Arctic region. In the last two decades, the Arctic region became a frontier for scientific discoveries and exploration studies. All circum-Arctic nations embarked on a quest for collecting new data and deciphering the structure and evolution of the Arctic crust and lithosphere. Along with bathymetric, gravimetric, and seismological studies, acquisition, processing, and interpretation of magnetic data are vital components for the understanding of lithospheric architecture. Modern magnetic data was collected and used in regional studies (e.g., Dossing et al. 2013), and to date, the circum-Arctic magnetic anomaly map (CAMP-GM) (Gaina et al. 2010, 2011), map based on airborne magnetic data, is still the only high-resolution magnetic data compilation available for the Arctic region (defined here as the region north of 60°). Updated World Digital Magnetic Anomaly maps incorporate an upward continuation (to 5 km) of the CAMP-GM compilation, or are using vintage, lower-resolution North Atlantic–Arctic magnetic anomaly maps (Lesur et al. 2016). Meanwhile, new global lithospheric models have been constructed based on satellite data. Due to the inaccessibility and harsh climate of this area, satellite data plays a crucial role for the Arctic science and examples of lithospheric models and their geological interpretation are shown below.

Figure 5 shows maps of magnetic anomalies recorded closer to Earth's surface (CAMP-GM compilation, Gaina et al. 2011), which display the magnetic signature of bodies in the Earth's crust, and magnetic anomalies measured from satellites (at 350 km from surface, as illustrated by the MF7 model (Maus et al. 2007), based on CHAMP satellite data, and at 460 km, shown by the LCS-1 model, based on CHAMP and Swarm data, (Olsen et al. 2017)), which image thicker than normal and/or deeply buried magnetic bodies. By upward continuing the magnetic data collected closer to the surface (either shipborne or airborne), a first-order estimation of shallow versus deep-magnetized bodies can be made.

Three profiles across Arctic continental and oceanic domains show how airborne and satellite magnetic data may help in identifying the nature and to estimate the thickness of main tectonic bodies (Fig. 5). Short wavelengths of airborne magnetic data detect magnetic anomalies due to seafloor spreading and dyke intrusions, and can be used together with other geophysical data (e.g., gravity or seismic data) to identify the transition between continental and oceanic lithosphere (Fig. 5). Seafloor spreading anomalies were previously identified in satellite magnetic

lithospheric models (see Maus et al. 2008), but the ultraslow spreading ridge in the High Arctic, the Gakkel Mid-Ocean Ridge, is imaged for the first time by the combined CHAMP and Swarm magnetic data (model LCS-1, Olsen et al. 2017), (Fig. 5). The oldest continental crust, usually found in the cratonic areas and as Proterozoic accreted crust, generates large positive magnetic anomalies, well visible in satellite lithospheric magnetic data. This crust contains large and deep volcanic bodies in the North American shield, Greenland, the Baltic shield in Eurasia, and the Siberian platform in NE Asia, which are now imaged in greater detail by the LCS-1 model (Fig. 5). One of the most striking features in the Arctic domains is the strong magnetic anomaly close to the North Pole that correlates with a large, igneous oceanic plateau called the Alpha Mendeleev ridge. The age and exact origin of this large igneous province is not known, although numerous studies speculate on an episode of Cretaceous volcanism that affected an old oceanic crust or a partially continental crust. This composite plateau generates the highest magnetic anomaly in the Arctic region (Fig. 5). The intensity and extent of the magnetic anomalies recorded by aircrafts or satellites point toward a very thick, volcanic crust. Magnetic anomaly data can be used to compute the depth to the magnetic basement, and in the case of Arctic large igneous provinces (LIPS) this can be as deep as 30 km (Li et al. 2017) (Fig. 5). Note that the results depend on the quality of input data and methodology. Although the new lithospheric magnetic model LCS-1 (Olsen et al. 2017) helps to better determine the overall location and extent of large magnetic bodies, only deep-sea drilling will be able to reveal the true nature of the underlying crust at the core of the Arctic.

The African continent. The African continent preserves a diversity of tectonic provinces, from ancient Archaean cratons and numerous orogenic belts to recent rifted areas like the East African rift system (e.g., Bouysse et al. 2010). However, comprehensive regional tectonic interpretations are hindered by the fact that large areas of the African continent are not accessible or simply not mapped in detail; considerable data gaps still persist in recent global compilations, including ground and airborne magnetic data (e.g., EMAG2v3 by Meyer et al. (2017), Fig. 6).

Higher-resolution lithospheric models based on satellite data (e.g., LCS-1 model, based on CHAMP and Swarm data, (Olsen et al. 2017)), shown in Fig. 6, provide continuous coverage and can image the regional tectonic domains with magmatic and metamorphic histories. High values of magnetic anomaly intensity displayed by the LCS-1 model are mostly associated with magmatic provinces (including LIPS, red outlines in Fig. 6 both on land and in oceanic domains). They also characterize the areas

Magnetic Modeling, Theory, and Computation,
Fig. 5 Lithospheric magnetic grids for the circum-Arctic region:

CAMP-GM ((Gaina et al. 2011) based on airborne data compilation upward continued at 2 km (upper left map)); MF7 ((Maus et al. 2007)

where old orogenic belts have been interpreted based on scattered geological evidences (as portrayed by the World Geological Map, e.g., Bouysse et al. 2010, dark grey polygons in Fig. 6). Some of these orogenic belts are in areas poorly or unmapped by geophysical data, like the Congo region in the central Africa (Fig. 6). The novel lithospheric models based on satellite data are therefore important tools to complement the geological models, and they increase our potential to better understand the spatial lithospheric heterogeneities and their role in tectonic evolution.

Conclusions

To model and interpret the Earth's magnetic field, two ingredients are crucial: global high-accuracy, high-resolution data and reliable mathematical tools.

Since 2013, a trio of satellites in the frame of the ESA Swarm mission provides a unique view inside the Earth. This

mission offers the most detailed data yet on the geomagnetic field of the Earth and its temporal evolution, giving new insights into improving our knowledge of the Earth's interior, thus the core and crustal fields. Their quasi-polar orbit allows to cover nearly entire Earth's surface; however, gaps still exist over the polar regions, inducing uncertainties on zonal coefficients. Another difficulty comes from describing the slow evolution of the external fields which limits the description of rapidly variations of the core fields.

These measurements together with those provided by magnetic observatories are valuable data essential for modeling the geomagnetic field and its interaction with other physical aspects of the Earth's system. Separating the signature of the different sources in both satellite and ground-based data can be done with a subtle weighting scheme of the many parameters entering this inverse problem, as shown here. The need of both high-resolution and complete datasets and continuously improved methods will allow us to better describe the spatial and temporal variations of geomagnetic internal field.

Definition

Magnetometers are devices/instruments that measure magnetic field/magnetic flux density in particular Earth's magnetic field either vectorially or scalarly.

Introduction

First measurements of magnetic field intensity have been introduced by Carl Friedrich Gauss (Kaufman et al. 2009) in 1834. He has established a number of magnetic observatories to continuously measure magnetic field of Earth (see ► “[Geomagnetic Field, Measurement Techniques](#)” and ► “[Geomagnetic Field, Secular Variation](#)”). Prior to that, compasses were in use for several centuries mostly for navigation but with no knowledge of the causes of magnetic needle behavior. Since Gauss' times, many methods of magnetic field measurement have been developed but there are two pillars of magnetometry discovered and developed in the twentieth century:

1. Fluxgate magnetometers for measurement of components of the vector of magnetic field (Primdahl 1979; Korepanov et al. 2007).
2. Scalar, quantum magnetometers with high precision of measurement and a possibility of measurements in motion (Abraham 1961; Alexandrov and Bonch-Bruевич 1992; Hrvoic 2004, 2008)

Presently, absolute measurements of magnetic field direction by optical methods (DI-Flux or DIM) based on fluxgate technology and the scalar measurements (Proton precession, Overhauser or Potassium) of its magnitude set up the limits of precision of the magnetic field vector measurement.

Magnetometry is a mature science/technology with myriad of applications. The need for better, more precise, smaller magnetometers fuels continuous research in the field.

This review will be treating separately vector and scalar magnetometers describing their principles of operation and main features, and with the view of their application in different fields of geophysical exploration.

Scalar magnetometers with their high precision and absolute accuracy now dominate measurements in mineral and oil exploration, volcanology, ordnance detection, archeology and partially magnetic observatories while vector magnetometer's role is limited to magnetic observatories, partially space measurement (Acuña 2002) (see ► “Equatorial Electrojet” and ► “Magnetic Methods, Principles”), and in vertical gradiometers for archeological research (see ► “Archaeomagnetism”). Scalar magnetometers are used to calibrate fluxgates. Some experiments with tensor measurements also include fluxgates and/or SQUIDs (Supercooled Quantum Interference Devices) (Clark 1993).

All modern magnetometers are computerized instruments with nonvolatile memory for display, storage, and review of data.

Scalar (Quantum) Magnetometers

Advent of scalar magnetometers in the second part of the twentieth century made a substantial contribution to measurement of both vector and scalar values of magnetic field. They offer precession frequency as a measure of magnetic field. Scalar magnetometer's sensitivities are determined only by achievable quality of precession signal, value of gyromagnetic constant, width of the spectral line (or time of decay of the precession signal), and signal-to-noise ratio. Scalar magnetometers have high sensitivity and accuracy of readings, virtually no drift with temperature or time. Measurements depend very weakly on sensor orientation or movement allowing for measurement in motion.

Proton, Overhauser, and Alkali metal (optically pumped) magnetometers are now overwhelmingly used in mineral/diamond/oil exploration, weapons detection, volcanology, archeology, magnetic observatories. Most of the current research is done in variations of optical pumping, and the progress in the last 25–30 years is phenomenal. Sensitivities have been improved from some nT to fractions of pT , perhaps four orders of magnitude, far exceeding requirements for ground (see ► “Magnetic Methods, Surface”), airborne (see ► “Magnetic Methods, Airborne”), or marine surveys. Speed of readings increased from perhaps once per second to tens and hundreds of readings per second limited only by increasing noise and/or possibility to usefully store a flood of data. With the development of instrumentation, the use of gradiometers with two or more sensors has increased (see ► “Magnetic Gradiometry”). It improves the quality of surveys, determination of depth of the anomaly producing body, following the direction and depth of the buried pipelines or electrical power lines etc.

Scalar magnetometer consists of a sensor, separated by a cable from electronics (to avoid its stray magnetic fields). Electronics has an analogue part that generates precession

Magnetometers, Fig. 1 Overhauser magnetometer – sensor, cable and electronics console

signal from the sensor and digital microprocessor based on part that controls the operation; measures Larmor frequency; converts it into units of magnetic field; and displays, stores, and/or outputs the data. Review of data is often possible (Fig. 1).

Global positioning plays a big role in geophysical ground and airborne surveys. In stationary measurements, GPS provides precise timing (1 μs accurate pulses referenced to Greenwich standard time).

Background Physics

Scalar magnetometers are all based on a spin of subatomic particles – electrons and protons (Abragam 1961; Schumacher 1970).

Spinning charged particles make magnetic dipoles. The dipoles are precessing around ambient (applied) magnetic field following Quantum Physics rules (Fig. 2).

Precession frequency is proportional to magnetic flux density:

$$\omega_0 = \gamma B$$

ω_0 is an angular precession frequency (Larmor frequency), B magnetic induction (flux density), and γ gyromagnetic constant.

Spinning protons (electrons) orient themselves in magnetic field. Only two angles of orientation are allowed: acute (lower energy level) and obtuse (higher energy level).

Since individual particles precess at random phases, their dipolar magnetic field in the plane perpendicular to the magnetic field is averaged out. A projection of the dipolar magnetic fields in the direction of the applied magnetic field is static. Since orientation at the acute angle to the direction of the field is more populated than the one at the obtuse angle, a minute “polarization” of precessing particles creates a magnetization M_0 collinear with magnetic induction B :

Magnetometers, Fig. 2 Magnetic moment μ of a proton (or electron) precesses around magnetic induction B . Resulting magnetization M is collinear with B and static. Components orthogonal to B are averaged out. Coupling energy $E = -\mu B$

$$M_0 = \frac{N\gamma^2 h^2 / 4\pi^2 B}{4kT\mu_0}$$

N is the number of particles, γ gyromagnetic constant, h Planck's constant, T absolute temperature, k , μ_0 constants.

When placed in the flux density B , M_0 will reach its "thermal equilibrium" exponentially with the "longitudinal" time constant T_1 .

When deflected by about 90° , it will precess around the field by the Larmor frequency and decay exponentially by the "transversal" time constant T_2 . (Time constants T_1 and T_2 depend on the aggregate state of the assembly of spinning particles. In liquids and vapors, they may be several seconds long, while in solids, T_2 time is only in milliseconds and the precession signal disappears very quickly. This is why all scalar magnetometers have liquid or gaseous sensors.) Particles at the lower energy level can accept energy in the form of magnetic field at Larmor frequency and flip to the higher energy level. Leveling of the two energy level populations eliminates M_0 . This is saturation of the precession spectral line. Proportionality constant, the gyromagnetic constant (not always a constant), is precisely determined to better than one part per million accuracy only for protons in water (Hrvoic 1996):

$$\gamma_p = 0.2675153362 \text{ rad/nT}$$

Magnetization M_0 is too small to produce detectable precession signal when deflected in the plane of precession. All scalar magnetometers therefore need to increase polarization and magnetization M and thus increase the sensitivity of the instrument. Polarization is increased in different ways:

- By temporarily increasing B to few hundreds Gauss (Proton magnetometers)
- Transferring thermal equilibrium polarization of electrons to protons in liquid sensors (Overhauser magnetometers)
- Using light polarization in alkali metals, and ^4He magnetometers

Proton Magnetometers

Proton magnetometers are the oldest scalar magnetometers. The first commercial units were produced in early 1960s as portable instruments. In continuation, airborne instruments appeared with optimized speed of readings and sensitivity, large sensors, etc. Later development of Overhauser and optically pumped magnetometers has eliminated Proton magnetometers from airborne surveys. However, they remain very popular in various ground surveys and observatories.

Proton magnetometer's sensor contains liquid rich in protons and polarization/pick-up coil. Polarization is done by increasing flux density B for a time comparable with T_1 of the sensor liquid. Electrical current passing through polarization coil creates strong magnetic field that polarizes protons of the sensor liquid. The coil is usually immersed in liquid to maximize the coupling. Alternatively, omnidirectional toroidal coil is used. Polarization field of few hundred Gauss must be roughly at the right angle to the measured field. Its removal must be fast to leave the newly formed magnetization in the plane of precession. Practical portable Proton magnetometers achieve about 0.1 nT sensitivity at a few seconds cycle, somewhat less in once per second measurements.

Overhauser Magnetometer

Overhauser effect originates from double resonance experiments in metals (Overhauser 1953). Russian and French scientists have greatly contributed to the development of modern Overhauser magnetometers based on nitroxide free radicals (Abragam 1961; Pomerantsev 1968). Practical realization of the magnetometer is as follows: Sensor liquid containing protons is placed in an RF resonator. It has small concentration of a Nitroxide free radical – stable chemical with one unpaired electron. The unpaired electron is dwelling close to the nitrogen nucleus, in its magnetic field of some 24 Gauss. Its electron paramagnetic resonance frequency in the Earth's magnetic field is about 30,000 times higher than the one of protons. Unpaired electrons couple with the protons of the sensor, creating a four energy level system (Fig. 3). Coupling can be either scalar or dipole – dipole. If one of them predominates, saturating electron resonance at some 60 MHz, transfers part of electron magnetization to protons. Increased proton polarization (magnetization) needs a 90° deflection to be turned in the plane of precession. The deflection can be either pulsed ($\pi/2$ pulse) or stationary by applying a weak rotating magnetic field of Larmor frequency in the plane of precession. Transferred magnetization is far superior to any

Magnetometers, Fig. 3 Four energy levels combined electron–proton system. Transitions 1–4 (weak scalar coupling) and 2–3 (dipole-dipole coupling) involve combined transitions of electrons and protons. 1–3, 2–4, 1–2, and 3–4 are independent transitions of electrons and protons

achievable by proton magnetometers and the measurement does not need to be interrupted for polarization; RF saturating field can be present continuously. In pulsed mode, repeated $\pi/2$ pulses interrupt measurement by about 25–30 ms. Low power consumption, no warm-up delay, higher sensitivity (10 pT for one reading per second), absolute accuracy, reasonable speed of readings (up to five readings per second), and omnidirectional sensors make Overhauser magnetometers very convenient and attractive for magnetic observatories, volcanological exploration, marine surveys, and base stations for airborne surveys. Oersted and CHAMP magnetic satellites use continuous Overhauser magnetometers as reference to vector measurement of magnetic field.

Optically Pumped Magnetometers

This is the latest to be invented and the most potent family of magnetometers. It consists of elements of the first column of the table of chemical elements. In gaseous form, alkali metals have an unpaired electron in their valence shell.

Gaseous sensor is subject to a circularly polarized light (D_1 line) (Happer 1972). Polarization process lifts electrons from a higher energy level to a metastable state from which electrons fall back to both levels.

Eventually, all electrons are in the lower energy level while the upper one is depleted. Absorption of light is then reduced and the sensor is more transparent. Rotating RF magnetic field of the Larmor frequency will depolarize the sensor and increase absorption of the light (Fig. 4).

As a result, the polarizing light will be modulated by the Larmor frequency. Its detection produces an electrical signal for the measurement of magnetic field. Helium 4 magnetometers that have two valence electrons need a weak discharge to

Magnetometers, Fig. 4 Optical polarization (lifting an electron from upper energy level to a metastable state) and depolarization (lifting electrons from lower to upper energy level) result in modulation of optical beam by Larmor frequency

lift one of them in a metastable state. Laser-pumped Helium 4 magnetometer has sub pT sensitivity. Due to the influence of nucleus (strong scalar coupling with valence electrons), all Alkali metal magnetometers have a number of spectral lines in their EPR spectrum (Breit and Rabi 1931).

Potassium spectral lines are well spaced and the operation of Potassium magnetometer can be based on a single narrow spectral line. This ensures very high sensitivity and the absolute accuracy similar to the one of Proton/Overhauser magnetometers. Cesium and rubidium lines are very close to each other, and they overlap and make a relatively wide composite single line. Operation of the magnetometer in self-oscillating mode is at the peak of the composite line. Problem is that the position of the peak depends on an angle between sensor axis and magnetic field direction. A heading error due to this effect can be reduced by a “split beam” technique, which symmetrizes the composite line. Reduction of the heading error to some nT or even a fraction of nT is possible. However, the split beam technique reduces the sensitivity by about one order of magnitude. Absolute accuracy of only few nT can be achieved by Cs and Rb magnetometers.

Measurement of Frequency

In the magnetic field of Earth (20–65 μT), precession frequency of protons is an acoustic frequency in a range of some 850 Hz–3 kHz, while Alkali metal optically pumped magnetometers produce 70–450 kHz, ^4He 280 kHz to about 2 MHz. Considering achieved precisions of measurement – one part per million or a small fraction of that for Proton and Overhauser magnetometers respectively and even few parts per billion for ^4He and ^{39}K or ^{41}K – we are resolving Larmor frequency to a millihertz precision. Times of all zero-crossings of precession frequency are taken, and an average period is measured by the least squares fit. Zero-crossing

times must be understood as a phase information too (0° , 180° , 360° , etc.), and this allows measurement to the sub Hz precisions. Measurement of phase difference to obtain the frequency results in an unusual noise dependence on the speed of readings. Most of measurements concerned with the noise bandwidth specify noise as per square root of Hertz. Doubling the bandwidth increases noise by square root of two. Not so in precession frequency measurement. When we double bandwidth by doubling the number of readings per second the noise increases by two square roots of two or $2^{3/2}$ instead of $2^{1/2}$. Defining noise as per square root of Hertz is therefore deceiving, although it may be calculated correctly for a particular number of readings per second.

Another peculiarity of precession frequency measurement is a phenomenon of “outliers” or “spikes” that occur when a zero-crossing time is either missing or modified by a spike of phase noise usually showing lower value of magnetic field. Preponderance of outliers increases dramatically as signal/noise ratio of precession signal decreases.

Absolute Accuracy and Precision

Absolute accuracy of measurement can be determined directly for Proton (Overhauser) magnetometers only. Proton gyromagnetic constant gets periodically refined by national standards institutions of a number of major countries (NIST, USA; NPL, U.K; VNIIM, Russia; NIIM, China).

Absolute accuracy of better than one part per million is possible to achieve. Besides the precise gyromagnetic constant, it requires a number of conditions to be fulfilled: sensitivity must always exceed the absolute accuracy, frequency reference precision must be adequate, phase stability of the signal and time determination of a zero-crossing must be proper, chemical shift of the precession frequency of the sensor liquid must be taken into account (Hrvoic 1996). Since we measure frequency of rotating magnetic moment, rotation of the sensor in the plane of precession introduces error (rotational Doppler). This error, insignificant for optically pumped magnetometers, may be significant for Proton and Overhauser magnetometers (about 23 nT offset for one cycle per second rotation of the sensor).

Alkali metal magnetometers have only potassium capable of high absolute accuracy (comparing its readings with Proton/Overhauser magnetometers) (Alexandrov and Bonch-Bruевич 1992). Cesium and rubidium operate on lumped spectral lines, (and ^4He has a very wide spectral line) and their absolute accuracies are in few nT range.

Great majority of nowadays measurements do not require high absolute accuracy but only sensitivity and repeatability or relative accuracy of readings. Exceptions are magnetic observatories, space measurements, and perhaps some standards measurements derived from magnetic measurements (determination of electrical current standard for example).

Sensitivities of scalar magnetometers vary. Details depend heavily on particular design, but an order of magnitude can be assessed. Proton magnetometers are nowadays used for ground exploration or calibration of vector magnetometers (fluxgates) only. Slow rate of readings can produce about 0.1 nT sensitivity and absolute accuracy. Up to two readings per second are possible, but at this rate, the noise is in nT range. Overhauser magnetometers achieve 0.01 nT at one reading per second, maximum rate five per second. High absolute accuracy Overhauser magnetometers are standard at magnetic observatories and very prominent in marine and ground surveys, and base stations for airborne surveys. Composite spectral line Alkali vapor magnetometers (Cesium, Rubidium) have similar sensitivity to Overhauser at one reading per second, but their top speed of readings is over 20/s. Their absolute accuracy is only few nT . Laser-pumped ^4He reaches sub pT sensitivities at one reading per second. Potassium has reached 0.05 pT sensitivity at one reading per second. Practical potassium assemblies for ground and airborne surveys feature sub pT once per second and about 7–10 pT rms noise at ten readings per second. Like cesium and rubidium, maximum speed of readings exceeds 20/s. Increase of noise is rather a practical limit to a number of readings per second. Cesium magnetometers are prominent in airborne surveys while potassium covers top of the field, especially in gradiometry due to its high absolute accuracy. Potassium is exclusively used in some new high sensitivity magnetic observatories and Earthquake study centers.

Vector Magnetometers

Vector magnetometers are generally used for static measurements (observatories) or in vertical suspension (archeology) or rarely in the component airborne surveys where only computed total field may reach 0.1 nT sensitivity, while components stay useless due to changes in aircraft attitude. In some recent attempt, accelerometers are used to account for attitude changes and apply corrections.

Main characteristics of most of the vector magnetometers are (except for SQUIDs):

1. Good sensitivity of measurement 0.1 nT common, 0.01 nT or somewhat lower (Korepanov et al. 2007) the best reported.
2. Very precise determination of the direction of measurement. One arc second change in direction means a fraction of one nT difference in readings, depending on an angle. In some orientations, vector magnetometers can resolve 0.01 nT field and well below one arc second angle.

3. Relatively substantial temperature dependence ($0.1 \text{ nT}/^\circ\text{C}$ or more).
4. Relatively substantial time variation – aging (2 nT or more per year).

Consequences of the above are difficulties in orienting in the magnetic field and determination of the orthogonality of the three components. Due to their temperature dependence/aging, the vector magnetometers at the magnetic observatories need calibration by Proton/Overhauser magnetometers.

Fluxgate Magnetometer

Main vector magnetometer today is the fluxgate. Its operation is based on nonlinearity of magnetic properties of steel (ferromagnetic material) (Primdahl 1979). When placed in strong magnetic field, steel will lose its high magnetic permeability in saturation, i.e., relative permeability will fall from several hundreds to close to one. A coil is wound around a layered core of steel, and alternating current is driving the core to saturation in two opposite directions alternatively. When not saturated, the core will concentrate the magnetic flux of the applied magnetic field. When saturated, the flux will deconcentrate itself. Pick-up coil wound around the core will detect changes in the flux passing through the core. With no external magnetic field, the saturations on positive and negative sides will be symmetrical i.e. the pick-up voltage will have only odd harmonics. When the external magnetic field is present, the saturations become unsymmetrical and second harmonic appears in the pick-up voltage, its amplitude proportional to the strength of magnetic field. Phase detected second harmonic is then a measure of applied magnetic field in the direction of the core. It is convenient to use two pieces of the core with excitation windings in opposition and the pick-up coil encompassing both cores as this eliminates pick-up voltage due to the original driving current. Instead of double iron core, a ring or “racetrack” shaped cores can be used (Fig. 5).

Today’s fluxgates can achieve $0.1 \text{ nT}/^\circ\text{C}$ temperature coefficient with some nT per year aging. Composition of the iron

cores plays a big role in the quality of fluxgates. Some recent new developments (Korepanov et al. 2007) claim better noise and aging characteristics.

During the Second World War, a total field – oriented single fluxgate was used to detect submarines. ASQ-10 instrument had about 0.1 nT sensitivity and the total field orientation of the sensor was kept by feedback electronics/mechanics.

Absolute Measurement

Declination/Inclination magnetometer (DI-Flux or DIM) is a variation of fluxgate measurement (Jankowski and Sucksdorff 1996). Fluxgate magnetometer sensor is mounted collinear with the optical axis of (nonmagnetic) theodolite, in horizontal plane. Theodolite is rotated, and two zero field angles are marked. The telescope is then reversed and two more zero readings determined. Magnetic north in arbitrary coordinate system is then calculated from angles of the four zero field measurements. The calculated angle is then referred to a known marker to determine true declination angle related to north direction. To determine inclination, the theodolite is oriented in just determined magnetic declination vertical plane and four zero field positions are determined in that plane. Averaging will give the angle off horizontal, i.e., the inclination. Some attempts have been made (see ► “Geomagnetic Field, Measurement Techniques”) to automate absolute measurements.

Simplified version of DIM is the Declinometer. It has a suspended magnet on a torsionless fiber, a mirror attached to it at the right angle to its magnetic axis and in front of a telescope. The theodolite is turned until the telescope becomes at right angle to the mirror. Direction of magnetic meridian is read from the base of the theodolite. This is referenced to a known reference mark to determine real declination angle.

Weakness of this measurement is an angle mirror-magnetic axis of the magnet that has to be 90° . This is mitigated by using two magnets of different magnetic moments.

Magnetometers,

Fig. 5 Excitation current drives the two cores (a) in saturation in opposite directions. Pick-up coil detects unsymmetry in saturation by measuring second harmonic. The cores can be connected at the ends to create “race track” (b) or ring core (c) shapes. Ring core allows for measurement of two orthogonal components, on one core

Magnetometers, Fig. 6 DIdD Overhauser/Potassium suspended system (a) and with external vertical coil to measure inclination directly (b)

Quantum Vector Magnetometers

SQUID is a vector magnetometer of exceptional fT range sensitivity. It operates at cryogenic temperatures (liquid helium or liquid hydrogen) (Clark 1993). It is used sporadically in geophysics for tensor calculations or short base gradiometers.

DIdD (Delta inclination delta declination) is a vector magnetometer with two orthogonal bias coils and a scalar magnetometer (Overhauser or Potassium) (Fig. 6).

Coils are oriented at right angles to magnetic field direction, one in a horizontal plane, one in vertical magnetic declination plane. A sequence of four biased fields and one unbiased allows for determination of departures of the field from the preset one. Orientation of one bias coil in the vertical direction and the other in the horizontal East-West direction (now possible with the precise GPS direction determination or a North seeking gyroscope) will convert dIdD instrument into an absolute D and I instrument. Potassium magnetometer can provide superior sensitivity and absolute accuracy. The stability of the instrument as for temperature and aging can be superior to the best fluxgates. This instrument is still in development. It is meant for use in the directional drilling for oil and minerals and possibly in a refined version for magnetic observatories.

Summary

Magnetic measurements are an essential part of geophysical exploration for minerals and oil, archeological, volcanological explorations, research of atmosphere, Sun's influence, crustal studies, earthquake research, etc. Scalar

magnetometers are dominant in most fields. They are described in some detail – their physics, principles of operation, details of design, sensitivities and absolute accuracy. Vector magnetometers are essential in magnetic observatories, space measurements, and many scientific investigations. Fluxgate magnetometers and variations of absolute determination of magnetic field direction have been described in some detail. Quantum magnetometers as vector magnetometers are briefly described. Refinement of Potassium magnetometers may improve sensitivity of presently used scalar magnetometers by two orders of magnitude to sub pT range.

Definition

Magnetotelluric data processing: statistical estimation and analysis of impedance tensors and other transfer functions from measured electromagnetic time-series data.

Introduction

In the magnetotelluric (MT) method (see “► [Magnetotelluric Interpretation](#)”), *data processing* generally refers to the initial analysis steps required to use naturally occurring time variations of electromagnetic (EM) fields measured at the surface to map the distribution of electrical conductivity within the Earth (see “► [Goelectromagnetism](#)”). The data are acquired as time series, generally including three components of the vector magnetic fields, along with the two components of the horizontal electric field. Earth conductivity variations have a relatively subtle effect on the

raw EM data, which most directly reflect the temporal pattern of external source variations. Sophisticated data processing methods have been developed to extract the interpretable Earth conductivity signal from these data. Two distinct steps can be distinguished. In the first, time series processing methods are used to estimate frequency-dependent linear relations or transfer functions (TFs), relating magnetic and electric field components. In the second step, distortion and strike analysis, the full set of TFs is reduced to a simpler set, consistent with simplified one or two-dimensional models of Earth conductivity, typically allowing for shallow near-surface complications. After these data processing steps, TFs are inverted for conductivity, and the resulting images are interpreted in terms of composition, physical state, and Earth structure.

MT Transfer Functions

The basic assumption underlying the MT method is that the external source fields are spatially uniform, an approximation that can be physically justified provided the spatial scale of external magnetic fields at Earth’s surface is large compared to the depth of penetration of the EM fields in the conducting Earth. Except at very long periods ($T > 10^4$ s), for which penetration depths in the Earth can exceed several hundred kilometers, and in the auroral zone where ionospheric current systems vary over short length scales, this assumption holds quite well for natural sources. Local cultural sources of EM noise have much shorter spatial scale, and will not always satisfy the uniform source assumption. These sorts of coherent noise, which violate the most fundamental MT assumption, represent the most serious obstacle to successful MT transfer function (TF) estimation.

For periodic sources at a fixed frequency, the assumption of spatial uniformity implies that sources can be expressed as linear combinations of two simple modes: unit magnitude uniform sources linearly polarized North–South and East–West. This in turn implies a linear relationship (in the frequency domain) between the horizontal electric and magnetic field vectors measured at a single site.

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} Z_{xx}(\omega) & Z_{xy}(\omega) \\ Z_{yx}(\omega) & Z_{yy}(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix} \quad (1)$$

The frequency-dependent 2×2 TF $Z(\omega)$ is referred to as the impedance tensor; see Fig. 1 for an example. Equation 1 can be justified by the linearity of Maxwell’s equations, and the assumption that all sources can be expressed as linear combinations of two linearly independent polarizations (Egbert and Booker 1989). Under these circumstances, two independent field components (e.g., H_x and H_y at one

Magnetotelluric Data Processing, Fig. 1 Example of an impedance tensor, the 2×2 TF relating horizontal electric and magnetic field components. Real and imaginary parts of the complex impedance components are plotted as a function of period. Note that the diagonal components of the impedance are relatively small; for the case of a 2D conductivity distribution, these components would vanish identically, if the impedance were expressed in the proper coordinate system

location) uniquely determine all other EM field components at any nearby site. The uniform source assumption thus also justifies other sorts of TFs. In the other most important case, the vertical magnetic field component is related to the two horizontal components at the local site

$$H_z = \begin{pmatrix} T_x(\omega) & T_y(\omega) \end{pmatrix} \begin{pmatrix} H_x \\ H_y \end{pmatrix}. \quad (2)$$

Vertical field TFs, which are commonly estimated along with the impedance in most modern MT surveys, are referred to variously as the Tipper, Parkinson vector, or Wiese vector. Inter-station TFs, which relate horizontal magnetic fields at two sites, are also sometimes considered (e.g., Egbert 2002).

Least Squares Transfer Function Estimation

The earliest approaches to MT TF estimation were based on classical time series methods (e.g., Bendat and Piersol 1971), applying a simple linear least squares (LS) fitting procedure in the frequency domain. To be explicit, consider estimating the MT TF between one component of the electric field (e.g., E_x) and the two horizontal magnetic field components H_x and H_y at a single fixed frequency ω . This TF corresponds to the first row of the usual MT impedance tensor. All of the discussion here and in subsequent

sections applies equally to the second row of the impedance, and to the vertical field TF. Because all of the TFs are most succinctly described in the frequency domain as in Eqs. (1 and 2), the first step in data processing is generally to Fourier transform the data. After possibly de-spiking and/or pre-whitening, time series for each component are divided into M short time windows, tapered, and Fourier transformed (Fig. 2). Fourier coefficients for N frequencies in a band centered around ω are used for the TF estimate, for a total of $I = MN$ complex data. Estimates $\hat{\mathbf{Z}}$ of the TF (i.e., impedance elements) are then obtained for frequency ω by least squares (LS) fitting of the linear model

$$\begin{pmatrix} E_1 \\ \vdots \\ E_I \end{pmatrix} = \begin{pmatrix} H_{x1} & H_{y1} \\ \vdots & \vdots \\ H_{xI} & H_{yI} \end{pmatrix} \begin{pmatrix} Z_{xx} \\ Z_{xy} \end{pmatrix} + \begin{pmatrix} \varepsilon_1 \\ \vdots \\ \varepsilon_I \end{pmatrix}, \quad (3)$$

or in matrix notation

$$\mathbf{E} = \mathbf{H}\mathbf{Z} + \boldsymbol{\varepsilon}. \quad (4)$$

With standard least squares (LS), this is accomplished by minimizing the sum of the squares of the residuals:

$$\sum_i \left| E_{xi} - (H_{xi}\hat{Z}_{xx} + H_{yi}\hat{Z}_{xy}) \right|^2 = \sum_i |r_i|^2 \rightarrow \min \quad (5)$$

yielding

$$\hat{\mathbf{Z}} = (\mathbf{H}^* \mathbf{H})^{-1} (\mathbf{H}^* \mathbf{E}) \quad (6)$$

where the superscript asterisk denotes the conjugate transpose of the complex matrix.

Robust Estimation

The simple LS estimator implicitly assumes a Gaussian distribution for the errors ε_i in Eq. (3). This assumption often fails for MT data due to the non-stationarity of both signal and noise. Both can be highly variable in time, resulting in a marginal error distribution in the frequency domain that is heavy tailed and contaminated by outliers. As a result, the simple LS estimate all too frequently leads to very poor TF estimates with large error bars (Fig. 3a). A number of MT processing methods have been proposed to overcome these difficulties, generally using some sort of automated screening or weighting of the data. Early efforts in this direction used ad hoc schemes, for example weighting data segments based on broad-band coherence between input and output channels. A more rigorously justifiable approach is based on the regression M-estimate (RME; Huber 1981), a variant on LS that is

Magnetotelluric Data Processing, Fig. 2 Example of time series collected with a long-period MT system. From bottom, three vector components of the magnetic field (measured with a fluxgate magnetometer), two colocated orthogonal horizontal electric field components (measured as the potential difference between pairs of electrodes separated by 100 m), and two horizontal components of the magnetic field at a distant remote site. Three overlapping data segments are indicated by

the vertical dashed lines. Segments such as these are Fourier transformed to yield a series of complex Fourier coefficients for each data channel, which are then used for the various transfer function estimates discussed in the text. Longer segments are processed to get Fourier coefficients for longer period data, typically after low-pass filtering and decimating the time series

robust to violations of distributional assumptions and resistant to outliers (Egbert and Booker 1986; Chave et al. 1987). For the RME, the quadratic loss functional of (5) is replaced by

$$\sum_i \rho \left(|E_{xi} - (H_{xi} \hat{Z}_{xx} + H_{yi} \hat{Z}_{xy})| / \hat{\sigma} \right) = \sum_i \rho(r_i / \hat{\sigma}) \rightarrow \min \quad (7)$$

where $\hat{\sigma}$ is some estimate of the scale of typical residuals. LS is a special case of (7), with $\rho(r) = r^2$. By choosing the functional form for $\rho(r)$ so that large residuals are penalized less heavily than with the quadratic used for LS, the influence of outliers on the estimate can be substantially reduced. For robust estimation of MT TFs, the so-called *Huber* loss function (Huber 1981)

$$\rho(r) = \begin{cases} r^2/2 & |r| < r_0 \\ r_0 |r| - r_0^2/2 & |r| \geq r_0 \end{cases} \quad (8)$$

is commonly used with $r_0 = 1.5$.

The more general loss function of (7) can be minimized with an iterative scheme, which can be viewed as weighted LS, with weights determined from the data. Define the *influence function* $\psi(r) = \rho'(r)$ (the derivative of the loss function), and set $w(r) = \psi(r)/r$. Then, it is easily shown that the minimizer of (7) satisfies

$$\hat{\mathbf{Z}} = (\mathbf{H}^* \mathbf{W} \mathbf{H})^{-1} (\mathbf{H}^* \mathbf{W} \mathbf{E}), \quad (9)$$

where $\mathbf{W} = \text{diag}[w_1 \dots w_I] = \text{diag}[w(|r_1|) \dots w(|r_I|)]$ is a diagonal matrix of weights. The RME thus corresponds approximately to the weighted LS problem $\sum_i w(|r_i|) |r_i|^2 \rightarrow$

$\min$. The weights depend on the normalized residuals $r_i = (E_{xi} - [Z_{xx}H_{xi} - Z_{xy}H_{yi}]) / \hat{\sigma}$, and hence on the TF estimate, so an iterative procedure is required. Given an estimate of the TF, and of the error scale $\hat{\sigma}$, normalized residuals can be used to calculate weights, and the weighted LS problem can be solved for a new TF estimate. This procedure can be started from a standard LS estimate of the TF (and some robust estimate of error scale, for example, based on the median absolute deviation of residuals) and then repeated until convergence.

For convex loss functions (e.g., the Huber function of (8)), convergence of this procedure to the unique minimizer of (7) is guaranteed (Huber 1981). For the Huber loss function in (8), the weights are

$$w(r) = \begin{cases} 1 & |r| < r_0 \\ r/r_0 & |r| \geq r_0 \end{cases}, \quad (10)$$

i.e., data corresponding to large normalized residuals get smaller weights. To allow for a sharp cutoff, with data exceeding a hard threshold discarded, the loss function $\rho(r)$ must be non-convex, and convergence of the iterative minimization algorithm cannot be guaranteed. The standard

practice is to iterate with a convex loss function such as (8) to convergence, followed by a final step or two with a hard cutoff to completely discard extreme outliers. This completely automated procedure frequently results in significant improvements in TF estimates, as indicated by improvements in smoothness and physical realizability of apparent resistivity and phase curves (Fig. 3b), and reproducibility of results.

More ad hoc schemes are also frequently used for down-weighting noisy or inconsistent data. These can be viewed as special cases of the weighted LS estimate of (9) but with weights now determined by some criteria other than residual magnitude. For example, in coherence weighting, broad-band coherence of input and output channels is used to down-weight time segments with low signal-to-noise ratios. Such methods can of course be combined with the RME.

Leverage

The RME can still be excessively influenced by a small number of data sections with large signal (or more typically noise) amplitude. In the terminology of linear statistical models, these large amplitude data are *leverage points*. For the LS estimate, the predicted data are

$$\mathbf{E} = [\mathbf{H}(\mathbf{H}^*\mathbf{H})^{-1}\mathbf{H}^*] \mathbf{E} \quad (11)$$

with the matrix expression in brackets (which maps observed data to predicted) referred to as the “hat matrix.” It is readily shown that the sum of the diagonal elements of the hat matrix satisfy $\sum_{i=1}^I h_{ii} = 2$, and that the individual diagonal elements h_{ii} can be interpreted as the fraction of total magnetic field signal power in the i th Fourier coefficient. Large values of h_{ii} indicate data points with inordinate influence on the TF estimates. In extreme cases, leverage points are used heavily to predict themselves, making the iterative RME ineffective. To deal with leverage points in routine MT processing, it is thus useful to include an additional weighting term (a function of the magnitude of h_{ii}) to reduce the influence of any observations of unusually large amplitude (e.g., Chave and Thomson 1989).

Remote Reference

The linear statistical model (4) is strictly appropriate to the case where noise is restricted to the output, or predicted electric field channels. Violation of this assumption results in the downward bias of estimated impedance amplitudes. These biases are proportional to the ratio of noise power to signal power, and can be quite severe in the so-called MT “dead bands” centered at frequencies 1–5 kHz and 0.1–1 Hz (examples of such biases are seen in Fig. 3a, b, at periods shorter than 20 s). To avoid these bias errors, horizontal magnetic fields recorded simultaneously at a remote reference site are correlated with the EM fields at the

local site (Gamble et al. 1979). Letting R_{xi} and R_{yi} be the Fourier coefficients for the two remote site components for the i th data segment, and $\mathbf{R}$ the corresponding $I \times 2$ matrix, then the remote reference analog of the LS estimate is

$$\hat{\mathbf{Z}} = [\mathbf{R}^*\mathbf{H}]^{-1}[\mathbf{R}^*\mathbf{E}]. \quad (12)$$

It can be shown that the remote reference estimate is unbiased if noise at the remote site is not coherent with noise in magnetic and electric fields at the local site. Thus, the remote reference estimate can eliminate or significantly reduce the effects of coherent cultural EM noise, provided the reference site is sufficiently distant. Very large scale sources of cultural noise, in particular DC electric railways, still present a significant challenge to collecting high-quality MT data in many parts of the world. These sources can be coherent over large enough scales to contaminate both local and remote signals, but still have significant power at wavelengths which are short enough to violate the MT uniform source assumption.

To generalize the RME to remote reference, one can iterate the weighted analog of (12), i.e., $\hat{\mathbf{Z}} = [\mathbf{R}^*\mathbf{W}\mathbf{H}]^{-1}[\mathbf{R}^*\mathbf{W}\mathbf{E}]$, weights on the diagonal of $\mathbf{W}$ determined from the residual magnitudes, exactly as for the single site robust estimator. It is also useful to add some additional weighting to allow for outliers at the remote site, and as with the single site estimates, for leverage. When arrays of simultaneously operating EM instruments are available, more complex procedures, which use data from multiple sites to define the reference fields are possible (Egbert 2002).

Error Estimates

With a statistical approach to TF estimation, one also obtains error variances that define the precision of the TF estimates. These error bars are required to assess the adequacy of fit of models derived by inversion, and thus play a critical role in the interpretation process. The covariance of the linear LS TF estimate of (6) is readily derived from standard theory, based on linear propagation of errors:

$$\begin{aligned} \text{Cov}[\hat{\mathbf{Z}}] &= \hat{\sigma}^2 [\mathbf{H}^*\mathbf{H}]^{-1} \\ \hat{\sigma}^2 &= (I - 2)^{-1} \sum_i |r_i|^2. \end{aligned} \quad (13)$$

where r_i are again the residuals. An analogous expression for the error covariance for the remote reference estimate is

$$\begin{aligned} \text{Cov}[\hat{\mathbf{Z}}] &= \hat{\sigma}^2 [\mathbf{R}^*\mathbf{H}]^{-1} [\mathbf{R}^*\mathbf{R}] [\mathbf{H}^*\mathbf{H}]^{-1} \\ \hat{\sigma}^2 &= (I - 2)^{-1} \sum_i |r_i|^2. \end{aligned} \quad (14)$$

Magnetotelluric Data Processing, Fig. 3 Comparison of TFs estimated from the same time series with three procedures described in the text: (a) standard unweighted LS; (b) the regression M-estimate applied to data from a single site; and (c) the robust remote reference estimate. Here, apparent resistivities $\rho_a = (\omega\mu_0)^{-1}|Z|^2$ and phases $\phi = \tan^{-1}(Z)$ are plotted, computed from the dominant off-diagonal impedances Z_{xy} (circles) and Z_{yx} (crosses). The LS estimates are too noisy

to be useful over much of the frequency range, while both of the robust estimates vary smoothly with frequency and have small error bars. However, the single site apparent resistivities of (a) and (b) are severely biased to low values for periods shorter than about 20 s. This bias is eliminated by the remote reference processing

For both (13) and (14), the diagonal components of the 2×2 covariance matrices are the estimation error variances for the two impedance elements.

For the RME, variances of the estimates are complicated by nonlinearity, but asymptotic expressions (valid in the limit of large sample sizes) can be obtained from standard theory (Huber 1981):

$$\text{Cov}[\hat{\mathbf{Z}}] = \frac{(I-2)^{-1} \sum_i w_i |r_i|^2}{[I^{-1} \sum_i \psi'(|r_i|/\hat{\sigma})]^2} [\mathbf{H}^* \mathbf{H}]^{-1} \quad (15)$$

where r_i , w_i , $i = 1, \dots, I$ and $\hat{\sigma}$ are the residuals, and weights and error scale from the final iteration, and the prime denotes the derivative of the influence function. An analogous asymptotic covariance for the robust remote reference estimates can be given with $[\mathbf{H}^* \mathbf{H}]^{-1}$ in (15) replaced by $[\mathbf{R}^* \mathbf{H}]^{-1} [\mathbf{H}^* \mathbf{H}] [\mathbf{H}^* \mathbf{R}]^{-1}$.

As an alternative to asymptotic error estimates such as (15), the nonparametric jackknife method (Efron 1982) has also been frequently used for computing TF error estimates (Thomson and Chave 1991). The jackknife approach can also be applied to compute error bars for complicated nonlinear functions of TFs, which arise, for example, in some forms of distortion analysis. The jackknife approach significantly increases computational effort required for TF estimation, unless some approximations are used (Eisel and Egbert 2001).

Strike and Distortion Analysis

As of this writing, MT data are most often acquired in profiles across a geologically appropriate strike, and the data are interpreted with two-dimensional (2D) Earth conductivity models that vary only with depth, and across strike, a reasonable approximation for many geologic structures. If the 2D assumption holds exactly, and the coordinate axes (used to give the components of the horizontal electric and magnetic fields) are chosen so that one of x or y aligns with the geoelectric strike (i.e., the direction along which there is no variation in conductivity), the diagonal components of the impedance tensor vanish.

$$\mathbf{Z}(\omega) = \begin{bmatrix} 0 & Z_{xy}(\omega) \\ Z_{yx}(\omega) & 0 \end{bmatrix}. \quad (16)$$

This special form only holds when the impedance is expressed in the proper coordinate system. Thus, once impedances are estimated, a key step in 2D MT interpretation is to determine an appropriate geoelectric strike where (16) holds approximately. The two off-diagonal components in this coordinate system (the transverse electric or TE mode,

in which electric currents flow along the geologic strike, and transverse magnetic or TM mode, in which electric currents flow across the geologic strike; *Magnetotelluric Interpretation*), are then fit using 2D modeling and inversion programs.

Even if the 2D approximation is reasonably justified for large-scale deep structure, more complex (3D) small-scale near-surface complications in conductivity will occur. These near-surface features result in distortion of the impedance tensor, so that even when the correct regional strike is used to define the coordinate system, the impedance tensor does not have the simple form of (16). Most modern approaches to 2D MT interpretation allow for these distortion effects in strike determination, and subsequent inversion. Early approaches to strike determination, such as choosing the strike angle to minimize the magnitude of the diagonal components, without accounting for distortion effects are seldom used anymore.

In the limit where the penetration depth of the EM fields greatly exceeds the depth to the bottom of the near-surface distorting structures, the electric fields (only) are distorted in a static (frequency-independent) manner. Allowing for rotation of the measurement coordinate system by an angle θ , the distorted impedance tensor for a 2D Earth can be decomposed as

$$\begin{aligned} \mathbf{Z}(\omega) \mathbf{z} &= \mathbf{U} \mathbf{D} \tilde{\mathbf{Z}}(\omega) \mathbf{U}' \\ &= \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix} \begin{bmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{bmatrix} \\ &\times \begin{bmatrix} 0 & \tilde{Z}_{xy}(\omega) \\ \tilde{Z}_{yx}(\omega) & 0 \end{bmatrix} \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}, \end{aligned} \quad (17)$$

where $\mathbf{D}$ is the distortion matrix, which is real, and $\tilde{\mathbf{Z}}(\omega)$ is the undistorted 2D impedance, which carries all of the frequency dependence. It is readily verified that not all of the parameters in Eq. (17) are uniquely identifiable – e.g., the distortion parameter D_{xx} cannot be determined independent of the absolute level of the impedance $\tilde{Z}_{xy}$; only the product $D_{xx} \tilde{Z}_{xy}$ is uniquely determined. However, (17) provides a suitable model to determine an optimal geoelectric strike (defined by the rotation angle θ), and this has ultimately become the most common use for strike and distortion analysis in most 2D MT interpretations. Note that in principal the same $\mathbf{D}$ and θ should apply to all frequencies at one site, while the strike angle should be the same over all sites.

Nonlinear least-squares estimation schemes can be used to fit the parameters in (17) (e.g., Smith 1995; McNeice and Jones 2001). These are often applied site by site, for various subsets of frequencies, but impedances from multiple sites can also be fit simultaneously. Finding a consistent strike provides justification, and an optimal coordinate system, for 2D interpretation. Sometimes, the analysis is also used to

eliminate sites, or frequency ranges, which are inconsistent with the generally preferred strike. Once the strike is determined and the impedance tensors are rotated, the off-diagonal components can be used as input for 2D inversion. Because the overall level of the impedance curves are still potentially effected by near-surface distortion, but the phases are not, it is common to fit phases more tightly, and relax fit to amplitudes (i.e., apparent resistivities). It is also possible to directly allow for distortion by introducing additional parameters at the inversion stage.

Summary

Data processing represents the first step in MT data interpretation, resulting in a reduction of the raw time-series data (approximately 10^6 observations) to frequency domain transfer functions such as impedances (a few hundred numbers). These transfer functions contain information about the response of the Earth to simple plane-wave sources, and provide input data for subsequent inversion and interpretation steps. Robust remote reference processing substantially improves reliability of transfer functions estimates. Except in areas of strong cultural noise (which unfortunately are increasingly common), modern processing produces smooth unbiased response curves. Distortion and strike analysis represents a further step in MT processing, essential for 2D interpretation of MT profile data. Such analysis is used to test for consistency with the assumed 2D geoelectric geometry, to estimate the strike, and to reduce the full impedance to the TE and TM mode responses appropriate to 2D interpretation.

Magnetotelluric Interpretation

John F. Hermance

Department of Geological Sciences, Brown University,
Providence, RI, USA

What Is Magnetotellurics?

The magnetotelluric (MT) method is a geophysical technique in which the time-varying electric and magnetic fields from distant natural or artificial sources are measured at the Earth's surface, and analyzed to determine the electrical properties of the subsurface.

Workers have known from the 1800s that naturally occurring transient voltages of significant magnitude observed on grounded telegraph wires were associated with rapid fluctuations of the geomagnetic field following *solar flares* and *auroral displays*. These natural voltage fluctuations – so-called telluric fields – have since been explained as the product of eddy currents induced in the finite conducting earth by transient magnetic field disturbances in the ionosphere and magnetosphere, even the global-wide propagation of radiated signals from lightning strokes in the distant atmosphere (see ► [“Electromagnetic Pulsations and Magnetic Storms”](#)).

Early work by Kato and Kikuchi, and Rikitake in Japan, and Tikhonov in the then, Soviet Union, laid the foundation for using these natural electric and magnetic field variations to study the electrical structure of the solid earth (see the collection of classic reprints by Vozoff 1985; see also ► [“Geoelectromagnetism”](#)). However, it was the seminal paper by Louis Cagniard (1953) that first described the

Magnetotelluric Interpretation,

Fig. 1 Schematic of a uniform plane wave vertically incident on the earth's surface

comprehensive procedure for using the ratio of the horizontal electric – that is, the *telluric* – field to the horizontal *magnetic* field, for which he coined the name the magnetotelluric method.

Fundamental Concepts: Surface Impedance and Apparent Resistivity

The magnetotelluric method, as generally employed by geophysicists, invokes several fundamental concepts from the theory of the propagation of electromagnetic waves. The first concept is the physical attribute known as the *electromagnetic wave impedance* of the medium (see ► “Magnetotelluric Data Processing”), provided by computing the ratio of the electric field intensity to the orthogonal magnetic field intensity. For example, Fig. 1 shows an electromagnetic plane wave vertically incident on the earth's surface; the electric field is polarized in the x -direction, and, to be consistent with the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, the magnetic field is polarized in the y -direction. Alternatively, for the case where the electric field might be polarized in the y -direction, the magnetic field will be polarized in the $-x$ -direction. The ideal natural field for magnetotellurics is one which is randomly polarized in *all* horizontal directions, so that usually both sets of electric and magnetic data, (E_x, H_y) and (E_y, H_x) , will be employed, leading to two estimates of the *surface impedance*:

$$Z_{xy}^{(\text{surf})} = \frac{E_x}{H_y} \text{ and } Z_{yx}^{(\text{surf})} = -\frac{E_y}{H_x} \quad (1)$$

The impedance terms in Eq. 1 can be looked upon as the coefficients of linear coupling relations between the electric and respective magnetic field components having the forms:

$$E_x = Z_{xy}^{(\text{surf})} H_y \text{ and } E_y = -Z_{yx}^{(\text{surf})} H_x \quad (2)$$

The subscripts on the impedance coefficients denote the ordering of the respective electric and corresponding orthogonal magnetic field components.

Under appropriate conditions, the *resistivity* of the uniform half-space in Fig. 1 may be determined from the measured surface impedance, since the *characteristic impedance* that a wave encounters traveling through a homogeneous medium is given by $Z_{\text{char}} = E_x/H_y = -E_y/H_x = \sqrt{i\omega\mu\rho_{\text{Tot}}}$ where $i = \sqrt{-1}$, ω is the radian frequency ($\omega = 2\pi f$, and $f = 1/T$ is the frequency in Hz, where T is the period in seconds), μ is the free-space magnetic permeability ($\mu = 4\pi \times 10^{-7}$ henries/m), and ρ_{Tot} is the total resistivity that accounts for both ohmic and dielectric effects in the medium.

The latter expressions for the ratios of the electric field to its orthogonal magnetic field counterpart, can be rearranged to estimate the resistivity of the medium according to $\rho_{\text{obs}} = (1/\omega\mu)|E_x/H_y|^2 = (1/\omega\mu)|E_y/H_x|^2$.

In general, however, the earth is *not* uniform, and as proposed by Cagniard (1953) in his classic paper, it is best to refer to the observed resistivity as an *apparent resistivity*, which might be determined using either combination of the respective field components, (E_x, H_y) or (E_y, H_x) . The corresponding apparent resistivities are commonly referred to as *Cagniard pairs*, and are given by

$$\rho_{xy}^{(\text{app})} = \frac{1}{\omega\mu} \left| \frac{E_x}{H_y} \right|^2 \text{ and } \rho_{yx}^{(\text{app})} = \frac{1}{\omega\mu} \left| \frac{E_y}{H_x} \right|^2 \quad (3)$$

For a uniform earth as well as for a plane-layered earth, as discussed below, one should expect that $\rho_{xy}^{(\text{app})} = \rho_{yx}^{(\text{app})}$. Exceptions to the latter denote the presence of lateral heterogeneities, also discussed below.

Principles of Depth Sounding

The *skin depth* or *depth of penetration* of an electromagnetic wave impinging on a uniform conductor (the earth) is given by $\delta \cong 500\sqrt{\rho \cdot T}$ meters, where ρ is the electrical resistivity of the medium in Ohm.m, and T is the period (inverse of frequency) of the signal in seconds. The consequence of the *skin-depth effect* is that low frequency (long period) waves penetrate to greater depth in a given conductor than high frequency (short period) waves (see ► “[Geoelectromagnetism](#)”).

The intrinsic resistivity of typical earth materials varies over many orders of magnitude, depending on mineralogy, water content, and temperature (see ► “[Electrical Properties of Rocks](#)”). Figure 2 summarizes the range of characteristic depths of penetration over the typical range of earth resistivities and frequencies employed in magnetotellurics. As an aside, note in the upper right corner of the figure, the roll-over of the linear isolines for high frequencies and high resistivities due to dielectric effects coming into play.

The *apparent resistivity* as a function of increasing period can be determined using spectral analysis of the measured electric and magnetic time series (see Vozoff 1985; see ► “[Magnetotelluric Data Processing](#)”). Then, from measurements of the apparent resistivity as a function of period, one can use the variable depth of penetration to electrically “probe” the earth to greater depth by progressively “tuning” the observed signals to progressively longer period.

For conventional magnetotelluric applications, at the highest frequencies ($\cong 1$ MHz) and the lowest resistivities (close to that of seawater, $1/3 \text{ } \Omega\text{-m}$, or lower), the signal (often from commercial or government radio transmitters, or, in the audio band, from distant lightning strikes) would penetrate to a few meters or few tens of meters depth. This range is useful for shallow geotechnical and groundwater investigations, and perhaps shallow geothermal work.

At the other end of the spectrum, at frequencies of a Hertz or lower ($T \geq 1$ s), workers usually rely on natural sources in the magnetosphere and ionosphere (such as micropulsations, magnetic substorms, and diurnal variations), (see ► “[Electromagnetic Pulsations and Magnetic Storms](#)”) to probe to depths of tens to hundreds of kilometers.

An example of the apparent resistivity that might be measured on the surface of a broad sedimentary basin as a function of period, as envisioned by Louis Cagniard in his 1953 paper, is shown in Fig. 3. The exploration geophysicist would have in mind that the relatively conductive sediments are underlain at some unknown depth by more resistive crystalline or metamorphosed basement (see ► “[Electrical Properties of Rocks](#)”). At an early stage, in the exploration of such a basin, the interpreter would like to determine three types of information from the observed MT data: *first*, the physical properties of the sedimentary basin (ρ_1 : the resistivity of layer 1); *second*, the depth d to the base of the sediments; *third*, the physical properties of the underlying basement (ρ_2 : the resistivity of layer 2). From the various models seen in Fig. 3b, a theoretical model with a surface resistivity of $10 \text{ } \Omega\text{-m}$, underlain by a more resistive $1,000 \text{ } \Omega\text{-m}$ layer at a depth of $1,000$ m, “fits” the observed data quite well. The mathematical framework through which one determines a model that best fits the set of observed data is known as *inverse theory* (see ► “[Magnetotelluric Data Processing](#),” ► “[Inverse Theory, Global Optimization](#),” ► “[Inverse Theory, Linear](#),” ► “[Inverse Theory, Monte Carlo Method](#),” and ► “[Inverse Theory, Singular Value Decomposition](#)”).

Effects of Lateral Heterogeneities

Early workers discovered the effects of lateral heterogeneities on MT data when they found that the Cagniard pairs were unequal: $\rho_{xy}^{(app)} \neq \rho_{yx}^{(app)}$ in Eq. 3. That is to say, the observed

Magnetotelluric Interpretation, Fig. 2 Depth of penetration as a function of frequency and resistivity of the host medium for geophysical applications

Magnetotelluric Interpretation, Fig. 3 (Panel a) An example of field data from magnetotelluric measurements. (Panel b) Field data overlaid on a set of theoretical curves representing various combinations

of model parameters, in this case the resistivity of each of two layers and the depth of layer 2

Magnetotelluric Interpretation, Fig. 4 Apparent resistivities along profiles transecting a vertical contact for two polarizations – TM and TE – of the source field relative to strike

apparent resistivity often depended on the direction in which the respective E and H fields were measured, as well as on the location of the measurements relative to local geologic features. Consider, for example, the case of the simple 2D vertical contact shown in Fig. 4. The observed apparent resistivities can be resolved into two principal modes: the incident electric source field may be polarized *perpendicular* to the strike of the contact, or it may be *parallel* to the strike of the contact in the y -direction.

Computing the corresponding apparent resistivities from the electromagnetic impedances for both cases, we obtain for the *TM* (Transverse Magnetic), or E-perpendicular mode:

$$Z_{xy}^{(\text{surf})} = \frac{E_x}{H_y}, \text{ leading to } \rho_{yx}^{\text{app}} = \frac{1}{\omega\mu} \left| \frac{E_x}{H_y} \right|^2 \quad (4)$$

and for the *TE* (Transverse Electric), or E-parallel mode

$$Z_{xy}^{(\text{surf})} = -\frac{E_y}{H_x}, \text{ leading to } \rho_{yx}^{\text{app}} = \frac{1}{\omega\mu} \left| \frac{E_y}{H_x} \right|^2 \quad (5)$$

Impedance matrix. Of course in actual field surveys one usually does not know ahead of time the trend or principal directions of local subsurface geologic features, so the electrode lines and magnetic sensors are usually deployed in standard geographic or geomagnetic coordinates. This leads to a “mixing” or “cross-coupling” of the field components. With reference to the linear coupling forms in Eq. 2, it is convenient to express these relations in the compact matrix form

$$\begin{bmatrix} E_x^{(p)} \\ E_y^{(p)} \end{bmatrix} = \begin{bmatrix} 0 & Z_{xy}^{(p)} \\ Z_{yx}^{(p)} & 0 \end{bmatrix} \begin{bmatrix} H_x^{(p)} \\ H_y^{(p)} \end{bmatrix} \quad (6)$$

where the superscript “p” denotes measurements in the principal coordinates of the feature (such as in the x - and the y -directions in Fig. 4). Rotating relation (6) through an arbitrary angle θ clockwise from the principal coordinates in Fig. 4 leads to a relation between the measured electric and magnetic field components of the form

$$\begin{bmatrix} E_x \\ E_y \end{bmatrix} = \begin{bmatrix} Z_{xx} & Z_{xy} \\ Z_{yx} & Z_{yy} \end{bmatrix} \begin{bmatrix} H_x \\ H_y \end{bmatrix} \quad (7)$$

where the *impedance matrix* is often referred to as a *tensor impedance*.

Three-dimensional (3D) heterogeneities. Recognizing that the earth is, in general, 3D, electromagnetic workers have developed various approximate methods to dealing with it since the 1930s (see Keller and Frischknecht 1966). Moreover, the theory of electromagnetic induction in 3D laterally heterogeneous material has evolved significantly over the decades since 1980, largely through implementing physically representative numerical techniques (see the work cited for Stodt, Wannamaker, Mackie and Madden among others, in Simpson and Bahr 2005; see also Siripunvaraporn et al. 2005). Several of the principal effects of three dimensionality are illustrated in the example in Fig. 5 which is a plan view map of telluric (i.e., electric) field distortions in the vicinity of

a small idealized, elliptically shaped conductivity anomaly in the surface layer of an otherwise uniform or plane-layered earth. The embedded “elliptical” feature in the figure is a modest four times more conductive than the host material (although it is not uncommon for lateral contrasts to be an order of magnitude or more). The important point is that the electric field (and the associated magnetic field) can change dramatically in magnitude and direction over very small distances.

Effects of bias of MT data from lateral heterogeneities. Workers realized early in the development of magnetotellurics that linear coupling relations like Eq. 7 are most often the rule in field data (see the collection of reprints assembled by Vozoff 1985). The first step, therefore, in interpreting MT data often involves decomposing multiple independent sets of observations of both of the electric field components ($E_x^{(obs)}, E_y^{(obs)}$) and the associated magnetic field components ($H_x^{(obs)}, H_y^{(obs)}$) to extricate estimates of the principal values of apparent resistivity, ρ_{xy}^{app} and ρ_{yx}^{app} , in the principal directions. It is common practice to plot up both resistivity estimates as a function of period, as was done for the plane-layered case in Fig. 3. However, the effects of even a small heterogeneity on the MT response of an otherwise plane-layered earth is illustrated in Fig. 6, using as the background the plane-layered example in Fig. 3 (shown as the dashed line in Fig. 6).

The dashed curve in Fig. 6a represents the original plane-layered response of Fig. 3, along with the hypothetical effects

Magnetotelluric Interpretation, Fig. 5 Plan view map of telluric (or electric) field distortions in the vicinity of an idealized embedded conductivity anomaly. (Panel a) Voltage contours and selected electric

field directions for a north-directed electric source field. (Panel b) The same parameters as panel a, but for an east-directed source field

Magnetotelluric Interpretation, Fig. 6 Examples of static bias. (Panel a) Example to demonstrate the mechanism of "quasi-static shift" (referred to the dashed plane-layered case). (Panel b) Selected

classes of "distortions" of MT data due to various combinations of shallow and deep lateral heterogeneities, with static and inductive coupling effects

that might be encountered in MT field data acquired at a site within, or in the vicinity of, a small, local embedded surficial anomaly. For one of the principal polarizations, the affected apparent resistivity relative to the original plane-layered curve is "upward-biased" by almost a factor of 2, and for the orthogonal polarization the apparent resistivity is "downward-biased" to 36% of its undistorted value. (There is no reason, of course, that for some cases both $\rho_{xy}^{app}(T)$ and $\rho_{yx}^{app}(T)$ might be biased to higher values, or both biased to lower values.)

Such bias effects are endemic to magnetotelluric surveys, and are particularly challenging to those investigations that are intended to be "deep-sounding" of the crust and upper mantle (and the mantle transition zones), since it is so easy for an undetected static offset to bias the long period asymptotic values to larger, deeper, and more resistive – or smaller, shallower, and more conductive – values. If, along with the "static" offsets described above, there are 3D induction effects as well, the field data become increasingly more complicated to untangle. Figure 6b shows several selected classes of MT responses often observed in field data due to quasi-static and inductive coupling effects for various combinations of shallow and deep (or distant) lateral heterogeneities. While one must be cautious in drawing too much from a single set of sounding curves, these panels might illustrate the following generic phenomena. Panel b1 illustrates the type of static shift from a shallow surface feature discussed above. Panel b2, on the other hand, suggests a fairly uniform layer at shallow depth, but as the period and depth of penetration increases, the principal resistivities begin to separate indicating a deeper-seated inhomogeneity. One needs to be careful here, as the inhomogeneity may lay off to the side, and be a lateral effect, rather than a simple

depth effect. Panel b3 suggests a similar, but more complicated phenomenon in that the two resistivity modes do not simply separate at longer period, but their respective shapes are frequency dependent, indicating that there are significant induction effects as well as static shifts coming into play. Panel b4 is an idealized version of situations commonly encountered in real data that might be theoretically explained by a true anisotropic resistivity layer at the surface, with a more conductive layer at depth. Often, however, for real world data, the merging of the principal resistivity curves with increasing period is simply a precursor to their crossing and then shifting apart again at still longer periods. In all of these cases, drawing 1D inferences from data that are clearly affected by 2D and 3D structure is questionable. For other examples, see Vozoff (1985) and Simpson and Bahr (2005).

Current Strategies for MT Interpretation

Much of the progress on MT interpretation over the last 3 decades is due to a progressive improvement in data acquisition, robust processing of multi-site data, and careful 2D and 3D numerical modeling. Simultaneously, recording multi-station MT arrays have become the standard practice for industry, academia, and government surveys. Recognizing the importance of high-density coverage using simultaneous observations of MT fields at multiple sites, several national programs are developing multi-station MT arrays. Typical instrumentation for such facilities is described by Smirnov et al. (2008), with some of the preliminary results of the Earthscope MT array in the United States reported by Patro and Egbert (2008) (See also ► "Instrumentation, EM").

There is an increasing emphasis, when interpreting MT data, on either explicitly using 3D models, or at least on using 3D models as guides when using the more efficient, less computationally intensive, 2D inverse techniques. The earth, however, *is* three-dimensional, and most workers agree that any attempt to simplify its inherent complexity with 2D or even 1D plane-layered models, needs to be assessed at some level with effective and representative 3D models. Such models have progressively evolved from the initial contributions reported in the reprint collection of Vozoff (1985). A number of notable reports on 3D numerical models – modeling, inversion, and applications – are contained in the compendium of Oristaglio and Spies (1995), with additional developments by Mackie et al. (1993), Siripunvaraporn et al. (2005), and Tong et al. (2009).

In spite of the promise of full 3D MT interpretations, most recognize that the inversion of data from a large regional array of broadband stations in terms of generalized 3D models tends to be computationally intensive (Newman and Alumbaugh 2000; Zhdanov and Tolstaya 2004). Thus, most surveys interpret array data in terms of 2D cross-sections. In many cases, the response of a 3D feature is locally quite 2D in nature. In other cases, it may be possible that the type of localized static shift discussed in an earlier section can be compensated for, and the observed coupling matrix can be decomposed into regionalized principal elements (Groom and Bailey 1989). Berdichevsky et al. (1998) summarize several of the major concepts that many interpreters employ when analyzing MT data from 2D (and 3D) environments. First, while the *TM* (*E*-perpendicular) mode is often quite sensitive to local near-surface features, the *TE* (*E*-parallel) mode is often more indicative of deeper, more regional features. Second, while the *TM* mode is more susceptible to the effects of static shift, it is not uncommon that the *TE* mode may be relatively undistorted. Both modes, however, are essential for a comprehensive interpretation of a study area, but must be used prudently. Ledo et al. (2002) discuss the limitations as well as the computational advantages – when appropriate – of applying 2D model inversions to actual 3D field situations.

For many investigations, the concomitant 2D and 3D effects might be considered unwanted “distortions” of deep-sounding data, and a bane to those studies intended to better understand the deep crust, or to delineate the depth to the lithosphere–asthenosphere boundary, the mantle transition zones, and so forth, on regional or sub-global scales. On the other hand, there is indeed a great deal of information in MT data that could be essential for characterizing the full 3D character of the earth, and the method, when properly executed, is proving to be a powerful means for delineating geologic features having application to a variety of fundamental geophysical and geological problems. However, it should be clear from the example in Fig. 5 that in order to identify, characterize, and account for the effects of localized surficial features, one needs to deploy a sufficient density of

sites to spatially characterize the surface field patterns. The situation is quite analogous to the “aliasing” problem that governs the strategy for properly sampling a time series; only in MT we are not dealing with simply a 1D sequence, but rather with 2D areal coverage. Berdichevsky (1999) offers a thoughtful critique of several of the underpinning paradigms and procedures of modern magnetotellurics.

Case Studies

A number of early applications of the MT method are described in the texts of Patra and Mallick (1980), and Vozoff (1985). More recent case studies are described in the text by Simpson and Bahr (2005). The most exciting of these involve multidisciplinary geophysical field efforts. Particularly, noteworthy is the series of integrated MT, seismic refraction, and gravity investigations initiated by the US Geological Survey in the Pacific Cascades volcanic belt in the Northwest US (see the review by Stanley et al. 1990). Early phases of this work led to the first major international offshore/onshore MT and geomagnetic deep-sounding (GDS) project: the EMSLAB project that extended from the offshore Juan de Fuca Rise to the east side of the Cascades volcanic system (*c.f.*, Wannamaker et al. 1989). Work in this area continues. For example, in a reanalysis of data from the EMSLAB Project, Vanyan et al. (2002) articulate the experience of many that when interpreting a profile of widely spaced, multi-site MT data in such complicated terrains, one needs to be selective in which elements of the MT impedance matrix are most consistent when developing a 2D inversion. They found that under the complex geologic conditions of the region, the strict inversion of both the *TE* and *TM* modes simultaneously at each and every site yielded an intricate, but what is likely a geophysically implausible, pattern of conductive and resistive features resulting in a large misfit of the model response to the data. The analysis improved significantly, they felt, when they were more selective in which of the principal impedance components were employed at a site. They also found that using lateral variations of the transient magnetic field, in conjunction with the MT data, significantly complemented their analysis. This point of view probably captures the spirit of most current MT investigations, and certainly underscores the importance of multiple station arrays of closely spaced sites.

In other regions, Sarma et al. (2004) report on a comprehensive MT study of an active seismic zone in western India. Solon et al. (2005) describe a large array MT study of the deep crust beneath the Himalayas in central Tibet. Munoz et al. (2008) investigate mid-crustal conductivity anomalies using 3D models of SW Europe. Wannamaker et al. (2008) describe the application of MT to understanding lithospheric deformation and magmatic processes along the Great Basin–Colorado Plateau transition zone. Continuing the work in the US Pacific

Northwest, Patro and Egbert (2008) report on their analysis of data from deployments in 2006 and 2007 of the still-evolving US Earthscope MT Transportable Array. Data were sequentially acquired in the period range from 10 to 10,000 s at 110 sites, covering the region at a nominal station spacing of 75 km. Han et al. (2009), using a 3D model to interpret MT data on the Korean peninsula, emphasize the importance of accounting for the effects of the nearby ocean and coastline. Eaton et al. (2009), in pulling together a variety of geophysical evidence, present a recent update on MT investigations of the lithosphere and asthenosphere beneath cratons, particularly for North America. Similar applications of MT to understanding significant solid earth problems are ongoing in China, Japan, Europe, Great Britain, South America, Antarctica, Africa, New Zealand, and Australia. Clearly, magnetotellurics is becoming an essential tool for a better understanding of earth systems on a variety of scales.

Summary

The magnetotelluric (MT) method is based on the physical theory of electromagnetic wave propagation in electrically heterogeneous materials. Using the “skin-depth” principle that, in a given conductor, long period signals penetrate to greater depth than short period signals, the method typically employs the rich spectrum of natural electromagnetic energy from the ionosphere, magnetosphere, and atmosphere (distant lightning storms) to “probe” the electrical structure of the earth from a few hundred meters depth to tens even hundreds of kilometers. For near-surface applications, active transmitters are used throughout the audio band (100 Hz to 20 kHz) to above a megahertz. The last decades have seen significant developments in the type of low-noise, large dynamic range instrumentation needed for such studies, along with robust real-time data processing, 3D numerical modeling, and geophysical inverse theory. The MT method involves recording and analyzing the spectral character of the complex amplitudes and phases of the electric and magnetic field components over a wide range of periods from an array of closely spaced sites on the earth’s surface. From the spatial and spectral character of such data, one can, in a sense, deconvolve the signatures of lateral and vertical variations in the bulk properties of the subsurface to develop insight on fundamental processes in the earth.

Magnetotellurics, Crustal Imaging

Prasanta K. Patro

CSIR-National Geophysical Research Institute, Hyderabad, India

Definition

Magnetotelluric (MT) imaging allows electrical characterization of the deep-crust and upper mantle, and can delineate and define fundamental blocks of crust, as well as major structural features like faults, suture zones, etc. The continental crust has been formed from mantle material over the lifetime of the Earth by a series of processes indicating melting, crystallization, metamorphic, erosional, depositional, subduction, and endless reworking events. Magnetotelluric method is sensitive to the conductive phases such as partial melt, fluids, and graphite. Therefore, MT provides highly useful models on electrical conductivity of the crust which serve as

complementary to other geophysical models such as seismic and thus helps in deriving realistic crustal models. MT has indeed been applied extensively to study several of the tectonically active regions including subduction zones, continental collision, rift zones, and also cratonic regions. There are many MT/LMT studies carried out globally to understand the crustal electrical signature related to different tectonic settings; however, in the following I have presented few representative examples.

Costa Rican Subduction Zone

Land and Marine MT studies were carried out to image the deep Costa Rican subduction zone (Worzewski et al. 2011) focusing on the hydration–dehydration cycle. Marine MT studies revealed the oceanic lithosphere – asthenosphere configuration which extends from shallow low resistive water saturated sediments lying over high resistive pillow lavas and sheeted dykes (A) which extend up to about 40 km depth reaching the upper mantle. At still deeper depths of about 80 km, a major low-resistive anomaly (B) is found which is attributed to the presence of asthenosphere with minor melt fraction.

In these zones prior to the subduction, during the bending of the subducting slab, deep faults are formed at mantle depths and water enters into these faults resulting in the hydration. This water is stored partially in the fractures and pores in oceanic sediments, crust, and serpentinized mantle. In the present case, the observed decrease in the resistivity (C) in the bending zone (Fig. 1) is interpreted to represent the serpentinized mantle rock. In contrast, during the subduction phase, water is released from cracks and pores when plate subducts to deeper levels, and this is referred to dehydration. While water released due to shallow phase transition reactions in sediments are stored at shallow depths (D), the dehydration of crust and mantle at deeper levels results in the deep-crustal fluid accumulation leading to generation of anomalous conductive regions (see G in Fig. 1). The conductive anomaly (G) thus represents the locally existent fluid accumulation associated with the fundamental dynamic processes in subduction zones. Tectonically, the deep crustal anomalous zone G may be considered to be closely linked to the development of surface expressions such as Volcanic arcs as shown in Fig. 1.

Ethiopian Rift and Afar

Afar and Ethiopian rift regions are generally considered to provide a natural laboratory to study the process of continental rifting and formation of new oceanic basin as a result of seafloor spreading. Dabbahu magmatic segment in the Afar region, Ethiopia, has been active since 2005 and witnesses

Magnetotellurics, Crustal Imaging, Fig. 1 Electrical image of Costa-Rica subduction zone from Land and Marine MT studies (Worzewski et al. 2011)

several dyke intrusion activities in central and southern parts of the segment. Desissa et al. (2013) carried out MT imaging of the region, using the TE and TM mode joint inversion using data space Occam inversion to obtain the resistivity structure of the crust/mantle column. Major finding in this study is the imaging of a large partial melt zone associated with the magmatic activity in the crust which is responsible for the dyke injections and volcanic eruptions in this region (see Fig. 2). The conductive pathways which are linked to the deep chamber are also delineated and they are shown to be correlating with the surface geological expressions such as volcano and dyke injections. B in the figure is the projection of Badi volcano in the study area on to the profile.

Himalayas

Himalayan mountain range is the classic example of the continent – continent collision and the resultant mountain building scenario. It formed as a result of collision between the Indian plate and the Eurasian plate during the Cenozoic

and it is still active. The Higher Himalayan mountain ranges exposing the high-grade gneisses were formed as the thrust sheet of Indian continental basement was displaced towards south along the MCT. Tethys Himalaya comprises Tethys sediments covering the Higher Himalayan crystallines (HHC). Indus suture zone comprises early tertiary granitoids of Ladakh plutonic complex. By inverting TM mode and Tipper data, Arora et al. (2007) observed a relatively resistive upper crust ($>300 \Omega m$) which represents granitic rocks of Ladakh Batholith and crystalline gneisses of Tethyan Himalayas. Besides this, the conductors were observed on both sides of the resistive Tso-Morari dome and these are interpreted as obducted ophiolite slab along the Main Zaskar back thrust.

In the MT models, the Indus suture zone is observed as a conductive zone dipping in the northeast direction and it merges with another conductive zone ($\sim 30 \Omega m$) in the mid-crustal column. But, Indus-Tsangpo Suture Zone (ITSZ) is not expressed as a conductive zone in the southern Tibet (Unsworth et al. 2005) as also in Leh region. This difference is explained as due to the weak postcollision deformation and

Magnetotellurics, Crustal Imaging, Fig. 2 Electrical signature of Ethiopian Rift system derived from magnetotellurics (Desissa et al. 2013)

comparatively slower convergence which might have preserved this near subvertical structure and extrusion along the southern margin of Tibet and this might be the reason for the absence of ITSZ in southern Tibet. The Main Himalayan Thrust (MHT) is observed as only moderately conductive zone dipping in the northeast direction in mid crust. Low resistivity is interpreted to be due to the accreted sedimentary rocks overlying the under thrust Indian plate. North of the Indus Suture zone, resistivity decreases further to 5–10 Ωm and it is interpreted as due to the presence of fluids or presence of a few percent partial melt beneath or the combination of both. The underlying lithosphere column is observed to be resistive reflecting the signature of crystalline rocks. Indian lithosphere extends to the Indus suture zone and tends to become conductive towards further north and this is interpreted to be due to shallowing of the asthenosphere in the region (Fig. 3).

San Andreas Fault

San Andreas Fault (SAF) is a continental transform fault acting as a tectonic boundary between Pacific plate and North American plate. Presence of fault-weakening fluids and frictionally weak minerals under the brittle crust are considered as the possible causes for the anomalously weak nature of the fault NW of Parkfield, California. Seismically active zones are observed near the Parkfield and the Cholame,

California. Nonvolcanic seismic tremor activities at lower crustal and upper mantle depths are observed in this region. MT studies are carried out in this region to understand the reasons behind the phenomenon and to evaluate the hypotheses (Becken et al. 2011). MT studies provided evidence for the fluid pressure induced seismicity near Cholame region. SAF near Cholame is observed to exhibit an anomalous resistivity feature extending to a depth of 20 km thus exceeding the brittle–ductile transition. Northwest of the Cholame, near SAF Observatory, an anomalously conductive zone (1–30 Ωm) at Depth was observed, extending from deeper to shallow levels in the region. The deep conductive region is interpreted as a fluid-filled zone formed as a result of dehydration of the serpentinized mantle wedge material. But near Cholame, the conductive fluid source region is bounded from above by the high resistive ($\sim 1000 \Omega\text{m}$) rocks, and interestingly the seismic tremors are concentrated in the high-resistive segments. So, the seismic activity is interpreted as due to the high fluid pressure and rock failure in mechanically strong region of high electrical resistivity as fluids migrate from a permeable, mechanically weak source to a mechanically strong region of high-electrical resistivity. Thus, hydrofracturing or reaction enhanced permeability are the suggested mechanisms for this phenomenon operating under high confining pressure in the lower crust and upper mantle. So, the periodic tremor activity observed close to the fluid source reflects the failure mechanism occurring due to the cyclic fluid pressure accumulation and release (Fig. 4).

Magnetotellurics, Crustal Imaging, Fig. 4 Two-dimensional resistivity cross-section at SAFOD (a) and near Cholame (b) (Becken et al. 2011)

Magnetotellurics, Crustal Imaging, Fig. 5 3D resistivity cross-section across Vestfold Hills and Rauer group, Antarctica (Modified from Peacock and Selway 2016)

Antarctica (Vestfold Hills and Rauer Group)

Archean to Neoproterozoic geological histories suggest the presence of a suture zone between Vestfold Hills and Rauer group beneath Sørsdal Glacier. MT studies were conducted to identify the exact location of the suture zone (Peacock and Selway 2016). Figure 5 shows the 3D model obtained. The top Ice cap of around 2 km thickness appears as a layer of resistivity less than the typical resistivity of pure glacier ice ($100,000 \Omega\text{m}$). The upper crust representing the crystalline rocks at crustal temperatures is moderately resistive ($<2000 \Omega\text{m}$). The conductive anomaly C1 appears at a depth of 6 km is interpreted to be due to sulfide minerals, sulfide grain-boundary film, and/or graphite grain boundary film within the dykes containing iron-rich and hydrogen-rich amphibole and clinopyroxene. The resistive zone R1, associated with suture, delineated beneath the Sørsdal Glacier is interpreted as the zone formed due to oxidation of the magnetite, sulfide, and graphite because of the high-temperature metamorphism occurred during suturing.

Dharwar Craton, India

MT and LMT studies were carried out across the Dharwar craton (DC) from the west coast to east coast in south India and also across the Eastern Ghat Mobile Belt (EGMB) to investigate the crustal and lithospheric structure and to identify the tectonic boundaries of different geologic domains (Malleswari et al. 2019). Modeling results brought out seven conductive features C1–C7 having resistivities between 100 and $1000 \Omega\text{m}$ within the highly resistive ($10^4 \Omega\text{m}$) background crustal column. These features are spatially

correlatable with the surface exposures of schist belts or granitic intrusions in the region and are interpreted as fossil pathways of the volcanic emplacements associated with greenstone belt and granite suite formations. The near-vertical conductive feature C8 under Chitradurga Shear Zone extending deep into the lithosphere is interpreted as mantle suture zone separating the western and eastern blocks of Dharwar Craton. Thick ($\sim 200 \text{ km}$) highly resistive lithosphere show typical Cratonic signature under Dharwar Craton, but intense lithospheric modification is also observed beneath western Dharwar craton. A major west-verging conductor identified beneath EGMB is interpreted to be the signature of Proterozoic collision process between the Indian landmass and East Antarctica. Lithosphere beneath EGMB is comparatively thinner ($\sim 120 \text{ km}$) and this might be due to Cretaceous rifting during break up of Gondwana supercontinent that resulted in the separation of India and Antarctica (Fig. 6).

Gawler Craton, Australia

A long-period magnetotelluric data set was obtained in 2005 across the western part of the late Archaean-early Proterozoic Gawler Craton, South Australia, with an aim of delineating the electrical conductivity structure of the crust and upper mantle underneath (Curtis and Thiel 2019). The MT measurements were made along an east-west trending profile extending from the Gawler Range Volcanics in the east, crossing the Nuyts Domain and the highly prospective Meso-Proterozoic Fowler Domain, and terminating in the Eucla Basin in the west. The electrical model shows a very high resistive crust and upper mantle underneath the Nuyts

Magnetotellurics, Crustal Imaging, Fig. 6 Electrical image of the Dharwar Craton, India (Malleswari et al. 2019)

Magnetotellurics, Crustal Imaging, Fig. 7 Two-dimensional resistivity model across the Gawler Craton, Australia (modified from Curtis and Thiel 2019)

and Fowler Domain, possibly representing the cratonic root of the Gawler Craton extending to depths of ~160 km. The resistive cratonic root is closer to the surface underneath the Fowler Domain compared to that in the Nuyts Domain which supports the findings derived from the study of outcrops of meta-sediments of higher metamorphic grade in the Fowler Domain. A subvertical conductor marks the western terminus of the Fowler Domain, and the feature is imaged to upper mantle depths. On the eastern side of the Fowler Domain, another subvertical conductor extends to similar

depths. These features spatially coincide with the Tallacootra and Coorabie shear zone at the surface, respectively, and their higher conductivity is likely due to a reduction in grain size of olivine associated with an increase in influence of grain boundary diffusion thus resulting in enhanced conductivity. A comparison of the results with those from seismic studies across mobile belts worldwide shows that the more resistive response of the interpreted mobile belt for the Fowler Domain raises questions as to the nature of the domain (Fig. 7).

Summary

In the active regions such as subduction zone, rift, and collision zones, MT studies delineated the conductive regions in the crust and upper mantle indicating the presence of pathways of fluid migration, large partial melt zone associated with magmatic activity. The suture/shear zones in the cratonic regions were reflected as a conductive zone in the crust representing the grain boundary diffusion (in the case of Gawler Craton; a resistive body caused due to metamorphism associated with suturing under oxidizing condition in the case of Antarctica, between Rauer Group and Vestfold Hills; a linear vertical conductive feature extending to upper mantle in the case of Dharwar Craton. Further, MT imaged the fluid-filled zones which are the genesis for the seismicity in the San Andreas Fault region. As could be seen from the foregoing, the MT models helped providing useful clues as to the nature and configuration of different subsurface geological and structural features in a wide range of complex tectonic scenarios. From shallow levels to much deeper levels extending into the deep crust and mantle. The results were integrated with other geophysical inputs particularly seismic helped to gain insights into the tectonic processes that led to the understanding of the genesis of seismic activity.

Magnetovariation Studies

Nandini Nagarajan

National Geophysical Research Institute, Hyderabad, India

Definition

Magnetovariation studies identify the induced component of magnetic variations, from a spatial array of magnetic variation measurements and thereby infer the distribution of subsurface electrical conductivity in the Earth, through a linear transfer function between inducing and induced variations. These induction studies, which investigate the secondary magnetic fields induced in the solid Earth by external current systems, are undertaken to provide constraints on the electrical conductivity of the upper 1000 km of the finitely conducting earth.

The techniques involved in magnetic induction studies are as follows:

- (i) Measurement of magnetic variations over an array of stations:

Variations of the earth's magnetic field, caused by processes in the ionosphere and beyond, viz.; external variations, and the secondary fields induced by them in the Earth are recorded at observatories or at magnetometer stations explicitly set up for the purpose (► [“Geo-magnetic Field, Measurement Techniques”](#)). The sampling interval and lengths of data recorded are determined by the depth of investigation desired, limitations of instrumentation, size of the array, etc. Electric currents flow through the Earth's magnetosphere and ionosphere causing a wide spectrum of external magnetic variations (~ 1 s – 1 day) (► [“Magnetic Methods, Surface”](#)). These secondary electric currents are induced, in the conducting Earth below the source current and can be identified from spatial gradients in magnetic variations measured at adjacent or nearby stations. The normal field is defined as the sum of contributions from the external source field and that part of the internal field, which is due to the regional (1D, radial variation) electrical conductivity structure.

- (ii) Spectral analysis of variations, sufficiency of signal content, based on assumptions regarding uniform inducing fields.

Spectral content of magnetic variation are estimated for desired lengths of time windows, after which spectra are smoothed, stacked over several time windows, and significant peaks in frequency bands are estimated. To compute these from magnetic variations at a single site, certain assumptions are made about both the external sources and the underlying conductivity distribution. The external variations are generated over large-scale lengths relative to the area of the study and the incident magnetic fields are assumed to be a plane wave. For very large arrays, some modifications to the analysis are required since this assumption may not be valid. Since a large volume of data is collected, where the properties of external variations may be nonstationary, a careful selection of data intervals of suitable characteristics, conforming to the assumptions above, is made. Several techniques to eliminate effects of nonuniform, time-varying characteristics of inducing fields, have also been evolved. Further, this spectral analysis provides insights into the character of external variations and their measurement over large spatial extent on Earth. A study of spectral estimates over large arrays has resulted in classification of long, intermediate, and short wavelength variations. From this accumulated knowledge, it is possible to assess the requirements of size and density of measurements before commencing surveys. The estimation of external field characteristics has also contributed to modelling of external variations. Spectral estimates are also examined to eliminate sources of nonuniformity and man-made noise.

The geometry, intensity, and period of induced anomalous variations depend both on the source and on the distribution of electrically conducting materials within the Earth. Inducing external magnetic variations cover a wide spectrum from minutes to days, thus creating induced responses over a wide spectral range. The longer period responses derive from deeper penetration of induced currents within the crust/mantle (► [“Magnetotellurics, Crustal Imaging”](#)). The spectral content of magnetic variations is therefore a useful natural tool to probe the earth’s interior.

- (iii) Computation of transfer functions:

For magnetovariation studies, lateral gradients of the magnetic fields are used to obtain estimates of electrical conductivity contrasts in the subsurface. The induced, anomalous field is generated by telluric currents flowing in non-one-dimensional conductivity

structures (2D/3D) and, thus, entirely of internal origin. This anomalous field is not uniform and affects both the horizontal and the vertical components – evident as spatial gradients, and may be subjected to noise from man-made sources. Transfer functions, usually estimated by least squares, indicate the relation between inducing and induced variations at a single site, multiple sites, and for signals not recorded simultaneously (hypothetical event analysis). Improved methods of determining transfer functions using robust statistical approaches, using the actual properties of the data, rather than ideal distributions have refined estimation of transfer functions, improving their reliability. Simultaneous observations also provide information on the spectral space of the data, in each array study, and indicate whether new or modified interpretation parameters are to be evolved for a particular study. Fitting these with a formal inversion procedure, along with more traditional single site parameters such as MT impedances and vertical field TFs, can enhance resolution of some features (► [“Magnetotellurics, Crustal Imaging”](#)).

- (iv) Modelling to obtain induced magnetic variations from the conductivity distribution – interpret in terms of geology and structure:

Magnetovariation studies primarily delineate contrasts in electrical conductivity in the subsurface. The depth and conductivity are poorly resolved. Therefore, this method is widely used as preliminary investigation of large- and small-scale anomalies, which may later be intensively investigated using more precise electromagnetic methods (e.g., Magnetotellurics). The conductivity anomalies investigated using magnetovariation often extend over 1000s of kilometers across continents, correlate tectonic signatures to deeper crust/mantle properties, and link events of the vast geologic time-scale. Many examples of continental scale structures, as well as sharply defined shallow crustal anomalies, that are directly related to tectonic events (faulting, seismicity) are discussed in good reviews (► [“Continental Crustal Structure,”](#) ► [“Electrical Resistivity Surveys and Data Interpretation,”](#) ► [“Magnetotelluric Interpretation,”](#) ► [“GPS, Data Acquisition, and Analysis,”](#) and ► [“Electrical Properties of Rocks”](#)). The principles of electromagnetic induction have also been applied to satellite data of denser spatial coverage. Here, the forward response of conductivity distribution is directly modeled and fitted to potential data. In this manner, induced contributions to crustal magnetization of continents and ocean crust have been estimated.

Interpretation

Magnetometer array studies provide geometry of induced currents, in the Earth's subsurface. The interpretation is not confined to any predetermined shape or single conductive feature, rather delineates broadly any lateral inhomogeneities in the upper 1000 km of the Earth's crust/mantle. The conductivities are poorly constrained in this method and need to be verified using other methods (e.g., MT).

The significance of these electrical conductivity contrasts are threefold:

- (i) Indicate change in composition within depth of penetration, more graphite/conducting minerals (Artemieva and Mooney 2001)
- (ii) Changes in temperature, at appropriate depth (Gough 1989)
- (iii) Indicates accumulation of fluids, interstitial, or within the metamorphic mineral structures (Jones 1992).

The above conditions and geometry of the conductivity anomaly are evaluated or eliminated, for the region under study. The significance of any or either of these conditions can impact the tectonics and evolutionary history of the region. The complementary nature of conductivity anomalies and other geophysical studies were established in the course of several Geotransects over ~1000 km continental-scale studies. The role of fluids in the crust has been a major contribution of these studies. (► “Continental Crustal Structure,” ► “Heat Flow, Continental,” ► “Seismic Velocity and Temperature Relationships,” ► “Continental Crustal Structure,” ► “Lithosphere, Continental,” ► “Electrical Properties of Rocks,” ► “Deep Seismic Reflection and Refraction Profiling,” and ► “Lithosphere, Continental: Thermal Structure”).

Summary

At the Earth's surface magnetometers measure the composite of external (from the external source currents) and internal (from the induced currents) field components. The observed magnetic field can be considered as the sum of a normal plus an anomalous induced field. Induced currents in the finitely conducting earth manifest as gradients in magnetic variations over spatial scales of ~10–1000 km.

The interpretation of electrical conductivity anomalies in the crust provide additional insights into the nature of the Earth's crust. In the upper crust (<15 km), most conductivity anomalies were correlated with deeper extensions of tectonic elements (faults, sutures) and compositional changes. Simultaneously, the phenomenon of seismic reflectors within the lower crust were found, and combined with

this, the significant role of fluids in the lower crust/upper mantle came to be recognized. A number of Geotransects across continents were carried out in 1990s and the complexities of evolutionary history on the lower crust were revealed. The relationship between electrical conductivity, high heat flow, seismic parameters, and tectonic history were formulated. Induction studies and later magnetotelluric soundings have contributed to an understanding of processes in the Earth's crust and upper mantle. This was also possible because of the refinements in instrumentation, data processing, and computational approaches in magnetovariation studies. Specific case studies from Geotransects and regional studies are described in detail in several reviews written on this subject.

Mantle convection Thermal convection in the terrestrial planetary mantles, the rocky layer between crust and core, in which hot material rises, cold material sinks, and the induced flow governs tectonic and volcanic activity, as well as chemical segregation and cooling of the entire planet

Introduction and History

All planetary bodies retain some heat from their early formation but are inexorably cooling to space. Planetary surfaces are therefore cold relative to their hotter interiors, which thus undergo thermal convection wherein cold material is dense and sinks, while hot material is light and rises (liquid water near freezing being one of the rare exceptions to this process). Planetary atmospheres, oceans, rocky mantles, and metallic liquid cores convect and are subject to unique patterns of circulation in each domain. Silicate mantles, however, tend to be the most massive and sluggish part of terrestrial planets and therefore govern how planetary interiors evolve and cool to space (see Fig. 1).

The theory of mantle convection was originally developed to understand the thermal history of the Earth and to provide a driving mechanism for Alfred Wegener's theory of continental drift in the 1930s (see Schubert et al. 2001; Bercovici 2015). Interest in mantle convection waned for decades as Wegener's theory was criticized and apparently discredited. However, the accumulation of seafloor sounding data during World War II and refinement of paleomagnetic techniques paved the way for the discovery of seafloor spreading (Dietz 1961; Hess 1962; Vine and Matthews 1963; Vine 1966) and the birth of the grand unifying theory of plate tectonics in 1967–1968 (McKenzie and Parker 1967; Morgan 1968; Le Pichon 1968); this consequently revived interest in mantle convection as the driving mechanism for plate motions (Runcorn 1962a, 1962b) as well as non-plate tectonic volcanism such as the possible Hawaiian plume (Morgan 1971). The success of mantle convection theory in explaining plate

velocities, seafloor subsidence, volcanism, gravity anomalies, etc. leads to its further application to other terrestrial planets such as Venus and Mars, which also sustained unique forms of mantle convection, evident from volcanic activity.

Basics of Thermal or Free Convection

Rayleigh-Bénard Convection

The simplest form of thermal convection is referred to as Bénard convection named after the French experimentalist Henri Bénard, who in 1900 performed the first systematic experiments on convection in thin layers of oil (spermaceti) and recognized both the onset of convection from a static conductive state and the regular patterns formed in a convecting layer (Bénard 1900, 1901). Fifteen years later, the British theoretical physicist and mathematician Lord Rayleigh (John William Strutt) attempted to explain Bénard's results for the onset of convection (Rayleigh 1916) – the delay in communication between them being caused by World War I. However, the mismatch between theory and experiment was significant and not resolved until the late 1950s (Pearson 1958) when it was inferred that Bénard's experiments were influenced by surface tension or Marangoni effects not included in Rayleigh's theory (although Bénard himself was aware of these effects). Because Rayleigh's work provided the framework for nearly all thermal convection theory to follow, the simple Bénard convective system is also referred to as Rayleigh-Bénard convection.

Although Bénard's experiments were in a metal cavity, Rayleigh-Bénard convection actually refers to Rayleigh's idealized model of a thin fluid layer infinite in all horizontal directions such that the only intrinsic length scale in the system is the layer thickness. The Rayleigh-Bénard system is heated uniformly on the bottom by a heat reservoir held at a fixed temperature (i.e., the bottom boundary is everywhere isothermal), and the top is likewise held at a fixed colder temperature by another reservoir (see Fig. 2). If the layer was not fluid, heat would flow from the hot boundary to the cold one by thermal conduction. But since the fluid near the hotter base is (typically) less dense than the fluid near the colder surface, the layer is gravitationally unstable, i.e., less dense material underlies more dense material. To release gravitationally potential energy and go to a minimum energy state, the layer is induced to turnover.

Convective Onset and the Rayleigh Number

While the fluid in a Rayleigh-Bénard layer might be *gravitationally* unstable, it is not necessarily *convectively* unstable. Convective overturn of the layer is forced by heating but resisted or damped in two unique ways. Clearly, the thermal buoyancy (proportional to density contrast times gravity) of a hot fluid parcel rising from the bottom surface through colder

Mantle Convection, Fig. 1 Graphic cut away of the Earth's structure showing crust, mantle, and core. The relevant dimensions are that the Earth's average radius is 6371 km; the depth of the base of the oceanic crust is about 7 km and continental crust about 35 km; the base of the lithosphere varies from 0 at mid-ocean ridges to about 100 km near

subduction zones; the base of the upper mantle is at 410 km depth, the transition zone sits between 410 and 660 km depths; the depth of the base of the mantle (the core-mantle boundary) is 2890 km; and the inner core-outer core boundary is at a depth of 5150 km. Image adapted from Lamb and Sington (1998)

surroundings acts to drive convective overturn. However, viscous drag acts to slow down this parcel, and thermal conduction, or diffusion, acts to erase its hot anomaly (i.e., it loses heat to its colder surroundings). Thus, while the fluid layer might be gravitationally unstable, hot parcels rising might move too slowly against viscous drag before being erased by thermal diffusion. Similar arguments can be made for cold material sinking from the top surface through warmer surroundings. The competition between forcing by thermal buoyancy and damping by viscosity and thermal diffusion is characterized in dimensionless ratio called the Rayleigh number

$$Ra = \frac{\rho g \alpha \Delta T d^3}{\mu \kappa} \quad (1)$$

where ρ is fluid density (units of kgm^{-3}), g is gravity (units of ms^{-2}), α is thermal expansivity (units of K^{-1}), ΔT is the difference in temperature between the bottom and top surfaces, d is the layer thickness, μ is fluid viscosity (units of Pa s), and κ is fluid thermal diffusivity (units of $\text{m}^2 \text{s}^{-1}$).

Even though $\Delta T > 0$ (i.e., heating is from below and causes gravitational instability), Ra still must exceed a certain value, called the critical Rayleigh number Ra_c for convection to occur. For $Ra < Ra_c$, the layer is stable and transports heat

Mantle Convection, Fig. 2 Rayleigh-Bénard convection: initially conducting layer (top) and numerical simulation of convection (bottom)

Mantle Convection, Fig. 3 The critical Rayleigh number Ra_c for the onset of convection is a function of wavelength or size of the thermal perturbation to a static conductive state. For a layer with isothermal and free-slip (shear-stress free) top and bottom boundaries, the relationship is $Ra_c = (k^2 + \pi^2)^3 / k^2$ where $k = 2\pi/\lambda$ and λ are wavelength (Chandrasekhar 1961). Values of Ra above the Ra_c curve are associated with the

conductive layer being convectively unstable (perturbations grow), while below the curve the layer is stable (perturbations decay). The minimum in the Ra_c curve occurs at the wavelength of the first perturbation to go unstable as heating and Ra are increased; this wavelength is often called the least stable (or most unstable) mode

by conduction; for $Ra > Ra_c$, the layer will be convectively unstable and transport heat more rapidly via convection (see Fig. 3).

Although Ra_c varies depending on the mechanical nature of the horizontal boundaries (whether rigid or a free surface), it is typically of order 1000. This value is easily understood by considering the fate of a hot (or cold) parcel of size a and temperature anomaly ΔT . Dimensional analysis readily shows that the typical ascent rate of the parcel is $\rho g a \Delta T^2 / \mu$ (with

units of m/s). However, the rate that heat diffuses out of the parcel is κ/a (smaller parcels lose heat faster). The critical state occurs when these two rates are equal; i.e., if the buoyant ascent rate just exceeds the diffusion rate, the parcel should rise without being erased, but if the ascent rate is less than the diffusion rate, it will not rise very far before being lost. Therefore the critical state occurs if $\rho g a \Delta T^3 / (\mu \kappa) \approx 1$. Scaling purely by orders of magnitude, a small parcel of fluid can be assumed to be of order 10 times smaller than the entire

Mantle Convection,

Fig. 4 Sketch of temperature profiles, showing how convective mixing homogenizes the conductive mean temperature into a nearly isothermal state (if the fluid is incompressible) with thermal boundary layers connecting it to the cold surface and hot base (top frame). With no internal heating, the interior mean temperature is the average of the top and bottom temperatures; the effect of adding internal heating (bottom frames) is to increase the interior mean temperature and thus change the relative size and temperature drop across the top and bottom thermal boundary layers

layer, thus assuming $a \approx d/10$ leads to a critical condition for onset of convection of $\rho g a \Delta T d^3 / (\mu \kappa) \approx 1000$.

For the Earth's mantle, the typical average properties from which the Rayleigh number is constructed are $\rho \approx 4000 \text{ kg/m}^3$, $g = 10 \text{ m/s}^2$, $\alpha = 3 \times 10^{-5} \text{ K}^{-1}$, $\Delta T \approx 3000 \text{ K}$, $d = 2900 \text{ km}$, $\mu = 10^{22} \text{ Pa s}$ (dominated by the lower mantle), and $\kappa = 10^{-6} \text{ m}^2/\text{s}$ (see Schubert et al. 2001). Taken together these lead to a Rayleigh number of approximately 10^7 , which is well beyond supercritical; although the mantle viscosity is extremely high, the mantle is also very hot and very large and hence convecting vigorously.

Thermal Boundary Layers and the Nusselt Number

For a Rayleigh number Ra above the critical value Ra_c , convective circulation will mix the fluid layer, and the mixing and homogenization of the fluid will become more effective the more vigorous the convection, i.e., as Ra is further increased. With very large Ra and vigorous mixing, most of the layer is largely uniform and isothermal. (In fact, if the layer is deep enough such that pressures are comparable to fluid incompressibility, the fluid layer is not isothermal but adiabatic, wherein even without any heating or cooling, the

temperature would drop with fluid expansion on ascent and increase with fluid compression on descent.) Most of the fluid in the Rayleigh-Bénard system is at the mean temperature between the two boundary temperatures. However, the temperature still must drop from the well-mixed warm interior to the cold temperature at the top and to the hotter temperature at the bottom. The thin horizontal regions accommodating these jumps in temperature are called thermal boundary layers (Fig. 4).

Thermal boundary layers are of great importance in thermal (and mantle) convection for two reasons. First, the buoyancy of the system is primarily bound up in the thermal boundary layers since these are where most of the cold material at the top and hot material at the bottom resides and from where hot and cold thermals or currents emanate. Moreover, with regard to convection in the mantle itself, the top cold thermal boundary layer is typically associated with the Earth's lithosphere, the 100 km or so thick layer of cold and stiff mantle rock that is effectively divided into tectonic plates.

Second, since fluid in these boundary layers is near a horizontal boundary, most of the fluid motion is horizontal, and thus heat is only transported vertically across these thin

layers by conduction, but since the layers are very thin, such conductive transport is rapid. Indeed, the entire cycle of heat transport occurs by heat conducted through the bottom boundary layer, after which hot fluid in this layer becomes unstable and rises to form a convective upwelling that carries heat out of the boundary layer across the fluid layer and deposits it at the upper boundary, where the heat is then transported out of the system by conduction across the top boundary layer. The eventual heat flow (power output per unit area) out of the well-mixed layer is essentially $k\Delta T/\delta$ where k is thermal conductivity (units of $W K^{-1} m^{-1}$), $\Delta T/2$ is the temperature drop from the well-mixed interior to the surface, and we define $\delta/2$ to be the thickness of the boundary layer. By comparison, the thermal conduction across a static non-convecting layer is $k\Delta T/d$. The ratio of heat flow in the convectively well-mixed layer to the purely conductive layer is thus d/δ , which is called the Nusselt number Nu (named after the German engineer, Wilhelm Nusselt 1882–1957). The relation between Nu and convective vigor parameterized by Ra is important for understanding how convection transports heat and cools off bodies, including planets. Convective heat transport is often written as $Nu(k\Delta T/d)$, and in considering this relation, Howard (1966) argued that vigorous convective heat transport across the bulk of the well-mixed fluid layer is so fast it is not the rate limiting factor in releasing heat (only conduction across the thermal boundary layer is), and thus heat flow should be independent of fluid depth d ; this implies that since $Ra \sim d^3$ then $Nu \sim Ra^{1/3}$, which yields a convective heat flow $Nu(k\Delta T/d)$ that is independent of d . In general, since the fluid is conductive for $Ra \leq Ra_c$, one often writes that $Nu = (Ra/Ra_c)^{1/3}$ (although $Nu = 1$ for $Ra < Ra_c$), which is a reasonably accurate relationship borne out by simple experiments and computer modeling. This relationship also implies that the ratio of thermal boundary width to fluid layer depth is $\delta/d \sim Ra^{-1/3}$, which shows that the boundary layers become increasingly thin as convective mixing of the layer becomes more vigorous.

The relation of $\delta \sim Ra^{-1/3}$ applies to the horizontally averaged boundary layer thickness. However, boundary layers change with time or distance from their first formation, e.g., where an upwelling impinges on the top boundary. As the fluid in the boundary layer moves from an upwelling to a downwelling, it cools and the boundary layer thickens as more material cools next to the cold surface. The thickening depends on the thermal diffusivity κ (with units of m^2/s) and the residence time or age t near the cold boundary (i.e., time since leaving the upwelling). Simple dimensional considerations show that the boundary layer thickness goes as $\sqrt{\kappa t}$; this corresponds to the well-known $\sqrt{\text{age}}$ law for subsidence of ocean seafloor with age since formation at mid-ocean ridges, implying that seafloor gets deeper because of the cooling and thickening lithosphere.

Patterns of Convection: Upwellings, Downwellings, Plumes, and Slabs

When convection occurs, hot upwellings and cold downwellings will be separated horizontally by some optimal distance. If they are too close to one another, they induce too much viscous drag on and/or lose heat rapidly to each other; if they are too far apart, they must roll too much mass between them. The separation distance is also determined by heat transport in the thermal boundary layer between upwellings and downwelling. When hot upwelling fluid reaches the surface, it spreads laterally into the thermal boundary layer. As it travels horizontally, it cools to the surface and eventually gets cold and sinks into the downwelling; thus the upwelling-downwelling separation is also determined by the distance it takes for fluid to cool off and become heavy enough to sink.

The upwelling-downwelling separation distance or convection cell size is predicted by convective stability theory to approximately equal the layer depth d (a bit larger at the onset of convection but identically d as Ra becomes very large); i.e., the cell that is either least stable or thus most likely to convect (see Fig. 3) – or equivalently the cell that optimizes gravitational potential energy (and thus heat) release – is usually the cell that is as wide as it is deep.

Viewing a convecting layer from above, the upwelling and downwellings may be separated in various patterns, such as two-dimensional rolls (sheets of upwelling rolling over into sheets of downwelling and each cell counter-rotating with its neighboring cell). In the Rayleigh-Bénard layer, which is infinite horizontally, no one location of the layer should be different than any other one, so ideally the pattern should be a regular repeating tile; as there are only so many polygons that can form a repeating tile, the patterns usually involve convection cells in the shapes of rolls (already mentioned), squares, hexagons, and triangles (Fig. 5). Of course, non-ideality and irregularities can occur due to tiny imperfections, for example, in the boundaries, leading to irregular patterns.

In many instances the 3-D pattern of convection, especially in fluids where hot fluid is less viscous than cold fluid (as is true in many materials, including the mantle), the upwelling is in the form of a cylindrical plume at the center of a canopy of sheetlike downwellings, much like a fountain (e.g., see Fig. 5, left panel, frames d and e).

Plumes and Slabs in the Mantle: Simple View

The common occurrence of sheetlike downwellings and columnar upwellings in simple convection is crudely applicable to mantle convection. Subducting slabs are where tectonic plates sink into the mantle; these are analogous to the cold sheetlike downwellings seen in 3-D convection, although much more complicated by rheology, as discussed below. Hot narrow upwelling plumes, rising from the base of the mantle to the surface, are inferred to explain intraplate

Mantle Convection, Fig. 5 Patterns of convection from laboratory experiments in a rectangular tank by White (1988) (left) and numerical simulations in a spherical shell by Zhong et al. (2000) (right). The left panel shows a top view of several experiments, using a shadowgraph

technique in which dark regions are upwellings and bright regions are downwellings (see Davaille and Limare 2015). The right panel shows three isothermal surfaces to represent cold downwellings (blue), warm upwellings (yellow), and the hot surface of the core (red)

volcanism, as in Hawaii, as well as the fixity of these volcanic hotspots relative to each other (which suggests deep anchoring in the mantle). These mantle plumes are ostensibly analogous to the pipelike upwelling in simple 3-D convection but again more complicated by unique mantle properties. (See “Mantle Plumes” essay by Farnetani and Hofmann.)

The manner of upwelling at mid-ocean ridges or spreading centers deviates from the classical picture of simple Rayleigh-Bénard convection. In particular, ridges are narrow linear features that, for the most part, involve shallow passive upwelling (inferred from their weak gravity anomalies that suggest shallow isostatic compensation, i.e., they are floating on a shallow buoyant root). Ridges are likely best explained as being pulled and rifted apart passively from a distant force (ostensibly slabs) rather than involving a deep convective upwelling that pries them open.

Energy Sources for Mantle Convection and the Earth's Thermochemical History

Heat flow coming out of the Earth is measured by heat-flow gauges (measuring conductivity of rocks first and then thermal gradients in boreholes) both in continents and oceans (see Jaupart and Mareschal 2011; Turcotte and Schubert 2014). The total heat flowing out from beneath the Earth's surface is approximately 46TW (46 trillion Watts) (Jaupart et al. 2015), which is not a large number given the surface area of the Earth and is tens of thousands of times smaller

than the heat absorbed from the Sun. Nevertheless, the terrestrial heat flow represents the source of power driving dynamics inside our planet, including mantle convection (and hence tectonic, volcanic, and other geological activity) as well as core cooling.

The source of the Earth's internal heat is a combination of primordial heat left over from planetary accretion and formation (i.e., energy release from planetesimal collisions as well as gravitational energy release from core segregation) and heat generated by unstable radioactive isotopes, especially the isotopes of uranium (^{238}U), thorium (^{232}Th), and potassium (^{40}K), although the ^{40}K half-life is much shorter than the others and so generated a large heat pulse primarily in the early Earth. Because continental crust is originally formed by partial melting and chemical segregation of early mantle material (see the discussion below in a later section), these radioactive elements tend to be concentrated in the crust (i.e., melt more readily dissolves these elements than does solid rock, so they partition toward the melt). Thus, the crust itself produces a significant fraction of the net heat output through the surface; removing the crustal component leaves approximately 38TW emanating from the mantle and core (Schubert et al. 2001; Jaupart et al. 2015).

The relative contributions of primordial cooling and radiogenic heating to the mantle (and core) heat output remain an active area of debate even today and lead to various quandaries. The most direct estimate of the concentration of radiogenic sources (U, Th, K) is by looking at the concentration in chondritic meteorites, which come from the solar systems' main asteroid belt. Because these meteorites

have been largely unaltered for 4.5 Gyrs (i.e., unmelted), they are thought to be the same as the original building blocks of the terrestrial planets. The chondritic concentrations of U, Th, and K would allow for radiogenic heating to contribute 50% or less to the total heat output (Korenaga 2008); this is often called the Urey ratio, i.e., the ratio of radiogenic heat output to the total output. With radiogenic heating this small, the only way the mantle could be as hot as it is today – while also transporting heat as it does presently – is if it was very hot and nearly molten in the geologically recent past (a few hundred million years); this is geologically untenable, since petrological and geochemical analysis demonstrate the presence of solid rock and even liquid water in the early Earth (see Halliday 2001), which therefore ceased to be molten not long after its formation 4.5 billion years ago. This paradox has led some researchers to assume that the radiogenic sources are super-chondritic, i.e., to allow heat to be produced continuously throughout the past rather than by rapid cooling from a molten state (Schubert et al. 1980). Alternatively, researchers have sought ways to keep chondritic concentrations of U, Th, and K by arguing that heat transport in the past was different than it is today; for example, higher temperatures in the past might have allowed for more melting and thus more buoyant crust and/or stronger dehydrated lithosphere that kept the top part of the convecting mantle sluggish or immobile, hence bottling up primordial heat for much later release (e.g., Korenaga 2008; Sleep 2015).

Finally, the release of both radiogenic and primordial heat, again termed collectively “internal heating” (i.e., heat coming from the bulk of the fluid), means that the idealized Rayleigh-Bénard model of convection, where heating is only along the base, is inaccurate. The effect of internal heating in addition to “basal heating” is relatively straightforward to understand. While in the Rayleigh-Bénard model the temperature of the well-mixed interior is at the average of the two boundary temperatures, the addition of internal heating acts to heat up the well-mixed interior to a higher mean temperature. This puts the interior temperature closer to the hot bottom temperature but further from the cold top temperature; the effect is to create a larger temperature drop across the top thermal boundary layer than across the bottom one; in essence, the top boundary layer must conduct out heat injected through the bottom plus heat generated or released from the interior (Fig. 4). These very different boundary layers tend to cause more negatively buoyant and stronger downwelling currents and smaller and weaker upwelling currents; this effect seems to be borne out in the Earth by the presence of many large cold slabs driving plate tectonic motion with large thermal anomalies (of order 500 K) relative to fewer upwelling plumes with weaker (200 K) thermal anomalies (c.f. Ballmer et al. 2015; Hernlund and McNamara 2015).

Effects of Mantle Material Properties

Mantle Rheology

The entire mantle of the Earth is potentially a convecting and overturning fluid. However, the mantle is almost entirely solid (with some small portions of melting near the surface delineated by volcanism and possibly much smaller areas of melting at depth) and thus flows extremely slowly. (Indeed, the term fluid does not suggest a liquid state but refers to how a medium deforms, with other modes of deformation including, e.g., elastic, plastic, or brittle behavior; these do not necessarily correlate with states of matter, i.e., gas, liquid, and solid, each of which can display either fluid or elastic behavior depending on the nature of the deformation; e.g., atmospheric sound waves are elastic behavior in a gas.)

The solid-state viscous flow of the mantle is a complex process, and there are various mechanisms that permit such “irrecoverable” deformation (one of the definitions of viscous flow). A survey of mantle deformation mechanisms or “rheology” is beyond the scope of this essay (see Ranalli 1995; Karato 2008). However, in brief, the two primary deformation mechanisms are called diffusion and dislocation creep. In any solid-state creep mechanism, mobility depends on the statistical-mechanical probability that an atom in a crystal lattice will leave the potential well of its lattice site; the potential well itself is defined by electrostatic or chemical bonds inhibiting escape and Pauli exclusion pressure preventing atoms squeezing too closely to each other. Thus, mobility depends on the Boltzmann distribution measuring the probability of having sufficient energy to overcome the lattice potential well barrier, which is often called the activation energy (or, allowing for pressure variations, the activation enthalpy). This probability depends on the Arrhenius factor $e^{-E_a/RT}$ where E_a is the activation energy (J/mol), R is the gas constant (J/K/mol), and T is temperature; RT represents the thermal excitation energy of the molecule in the well. As T goes to infinity, the probability of escaping the well goes to 1 (meaning greater mobility and hence softer material), while as T goes to 0, the probability of escape goes to 0 (meaning less mobility and stiffer material).

Stress imposed on the medium effectively changes the shape of the potential well, such that compressive stress steepens the walls of the well (squeezing atoms closer makes coulomb attraction in the chemical bonds stronger), while tension lowers the walls (separating molecules weakens the bonds); thus, the probability of escape is preferred in the direction of tension and away from compression, allowing the medium to stretch in the tensile direction by solid-state diffusion of molecules.

Simple diffusive creep works much in this way where differential stress (i.e., nonuniform stress) causes slow diffusion of molecules to allow the entire substance to deform accordingly. However, such deformation occurs at the

mineral grain level inside a rock, with either diffusion through the grains or along the grain boundaries; thus the response depends significantly on grain size.

Dislocation creep is more complicated. Dislocations are a type of crystal defect associated with misalignment in the otherwise ordered rows of atoms in a crystal lattice; these can be in the form of truncated rows of atoms or other imperfections in the order by which atomic planes are stacked in the lattice. The presence of a dislocation gives rise to internal stress within a crystal, which adds to the ambient stress acting on the rock. To relieve these stresses, dislocations move through the crystal (one atomic step at a time), interact with each other by deforming the lattice in their vicinity, and trigger the formation of new dislocations. Their motion is also limited by the mobility of atoms in the lattice, and thus they obey a similar thermally controlled Boltzmann statistics and Arrhenius factor described above for diffusion creep. The generation and motion of dislocations are an efficient way to accommodate strain, known as dislocation creep. However, the combined influences of internal and ambient stresses on dislocation dynamics are compounded into a nonlinear rheological response, wherein stress and strain rate are not linearly proportional to each other.

The viscosities for diffusion and dislocation creep mechanisms can be written as

$$\mu = \begin{cases} Ba^m e^{\frac{E_a}{RT}} & \text{for diffusion creep} \\ Aa^{1-n} e^{\frac{E_d}{RT}} & \text{for dislocation creep} \end{cases} \quad (2)$$

where A and B are proportionality constants, a is grain size, σ is stress (in fact, since stress is a tensor, σ^2 is the scalar second invariant of the stress tensor), and m and n are exponents, characteristic values of which are both 3 ± 1 . It should be emphasized that diffusion and dislocation creep occur independently of each other depending on stress and grain size: for high stress and large grains, dislocation creep dominates; for low stress and small grains, diffusion creep dominates. Dislocation creep allows for moderate softening as stress increases; diffusion creep potentially allows for significant softening if stress can reduce grain size (see the sections below on generating tectonic plates).

One of the strongest rheological effects is that of temperature; the temperature dependence of viscosity allows for many orders of magnitude variations in strength. For example, while this rheological effect allows cold subducting slabs to keep their strength and integrity to great depths as they sink, it makes hot upwelling mantle plumes more fluid, and, if they have a conduit structure, the plume material ascent rate is relatively rapid, of order 100 cm/year or more. However, this effect is most profound in the cold top thermal boundary layer or lithosphere. If viscosity is strongly temperature dependent, as it is in the Earth, the lithosphere can become so stiff that it

becomes immobile; in this case convection in the mantle would proceed beneath the lithosphere, which in turn would act like a rigid lid to the mantle (Solomatov 1995). If temperature were the only property controlling the mantle's rheological properties, then the lithosphere would be locked and immobile, and there would be no plate tectonics. While this scenario might be relevant for Venus and Mars (and Moon and Mercury), which arguably have no plate tectonics, obviously it is missing a vital ingredient to allow plate tectonics on Earth. This paradox underlies the fundamental question and mystery about why the Earth has plate tectonics at all and how it is generated on our planet but not others in our solar system (Bercovici 2003; Bercovici et al. 2015; Mulyukova and Bercovici 2019).

Compressibility, Melting, and Solid Phase Changes

Pressures deep inside the Earth's mantle are so large; they are sizable fractions of rock incompressibility or bulk modulus (e.g., mantle pressures reach 140GPa, or 1.4 million atmospheres, while bulk modulus – which has the same units as pressure – are typically a few to several 100GPa). As downwelling mantle material travels from near the surface to the base of the mantle, its density and temperature increase due to compression, called “adiabatic compression and heating” (and likewise upwelling material undergoes “adiabatic decompression and cooling”), although these increases are not large (of order several degrees Celsius). The compression and decompression of circulating material establish a weak adiabatic temperature and density increase with depth, which has a slight stabilizing effect on convection; however, because the mantle is so viscous, the thermal anomalies needed to get it to move – and in particular the temperature variations across the thermal boundary layers – are so large (of order several 100 to 1000 degrees Celsius) that the adiabatic variations are small in comparison (Bercovici et al. 1992).

Where compressibility and pressure play a dual important role is in phase changes. First, as hot upwelling mantle material approaches the surface, it actually travels along a gradually cooling adiabatic temperature profile. The upwelling does eventually melt when it gets near the surface but not because it gets hotter. Melting occurs because the melting temperature T_m drops with decreasing pressure faster than the upwelling adiabat (in essence, decreasing confining pressure makes it easier for molecules to mobilize into a melt); thus at a certain usually shallow depth of a few 10s of km to 100 km, the upwelling mantle crosses the melting temperature from solid to liquid phase and undergoes melting; however, the mantle is not a single pure substance so only partially melts. The resulting liquid melt phase is expelled to the surface where it refreezes to make basaltic crust. Such “pressure release” melting is a shallow process but is vital for chemical segregation of the mantle and development of oceanic crust. (The production of continental crust is a more

complicated process resulting from the injection of hydrated minerals into the mantle at subduction zones; this triggers flux or hydrous melting of the mantle, which then – upon melt ascent through pre-existing crust – leads to a cascade of silica-rich melt products in volcanic arc environments.)

Extreme pressures with depth can also overcome a mineral's elastic resistance to compression and cause solid-solid phase changes in which the minerals change their crystallographic structure to a more compact, denser, and incompressible state (but their chemistry remains the same). Such mineralogical phase changes have been observed in laboratory experiments in olivine, which is the major mineral component of the upper mantle (at about 60% by weight, the remainder being mostly pyroxene at shallow depths, and garnet at slightly greater depth). The pressures at which these phase changes are predicted to occur have been verified seismologically; i.e., seismic wave speeds undergo a jump at the pressures where the phase transitions and density jumps are predicted to exist. The first major phase change to occur with depth is from olivine to the same material with a wadsleyite structure, at 410 km depth. Wadsleyite changes slightly to a similar ringwoodite structure at 510 km depth. The largest phase change occurs from ringwoodite to perovskite/magnesiowüstite at 660 km depth.

The 410 km and 660 km phase changes are the two most remarkable and global phase changes in the mantle, and the region between them is called the transition zone, since it is where most of the mineralogical transitions occur, over a relatively narrow region. The mantle above the transition zone is typically identified as the upper mantle, although in some papers and books upper mantle includes the transition zone. Below the transition zone is the lower mantle, and that is universally agreed upon in the literature. The transition zone has anomalous properties due to mixing and transitions in mineral organization; for example, it is thought to be able to absorb an order of magnitude more water (per kg) than the mantle both above and below it (Wood and Corgne 2015).

Other phase changes are thought to occur with depth, although these are less well resolved, and in some instances do not appear to be global. One of the most recently discovered phase changes has been inferred to exist in the lowest part of the mantle (the bottom few 100 kilometers), called the perovskite-post-perovskite (or just the post-perovskite) transition (Murakami et al. 2004; Hernlund and McNamara 2015). This transition is still an active area of exploration.

The effect of phase transitions on mantle convection has been an active area of research since the 1960s. The discovery of the major phase change at 660 km depth coincided with the fact that deep earthquakes along subducting slabs (the Wadati-Benioff zone) go no deeper than 700 km. This seemed to imply that subducting slabs, the mantle's equivalent of cold convective downwellings (see below), did not extend into the lower mantle. Recent seismological studies using

tomographic techniques to resolve ostensibly “cold” and “hot” areas of the mantle (really seismically fast and slow regions) implied that many slabs might stall or pool temporarily at the 660 km boundary, but many penetrate into the lower mantle (Fig. 6).

Whether the density jump due to a phase change could impede vertical flow has been a key question in studying the interaction of phase changes and convection. In particular, the 660 km phase change was inferred mineralogically to be “endothermic” whereby the entropy of the deeper heavier phase (below 660 km) increases, or more simply latent heat is absorbed on going down through the boundary into the denser more compact phase (while unusual in most systems, this is also true of the solid-liquid transition in water). This also means that the dependence of the transition temperature on pressure has a negative slope; thus cold material impinging on the phase boundary causes the phase change to deflect in the cold region to greater pressures; this induces a depression in the boundary that acts to buoyantly rebound upward and oppose the motion of the descending cold material. Thus the endothermic boundary at 660 km depth possibly impedes flow across that boundary (Schubert et al. 1975) (However, the actual 660 km phase change is complex and at higher temperatures might become exothermic (Weidner and Wang 1998).) Computational studies and simulations of mantle flow across this boundary demonstrated that downwellings (i.e., slabs) can indeed be impeded and stalled as they impinge on this boundary, but not permanently or globally; i.e., while some downwellings pool at the boundary, others accumulate enough “weight” to push through the boundary (Tackley et al. 1993; Christensen 1995). This picture appears to be in keeping with seismological findings, wherein some slabs appear to stagnate, pool, or deflect from their vertical descent at the 660 km boundary, while others appear to penetrate the boundary into the lower mantle (e.g., van der Hilst et al. 1997; Fukao and Obayashi 2013). Therefore, while that phase boundary impedes slabs and downwelling flow into the mantle, it is not an impermeable boundary, and there is, in the end, significant exchange between the upper and lower mantle and hence whole mantle convection.

However, while the mineralogical, seismological, and geodynamical (fluid mechanical) arguments imply that there is flow between upper and lower mantles, there are numerous data from geochemical analysis of basaltic lavas implying that the mantle is not well stirred on a large scale, i.e., it is possibly layered with poor or nonexistent communication between upper and lower mantle.

Mantle Geochemistry and Mantle Mixing

Upwelling mantle reaching the Earth's surface undergoes melting (see above under pressure-release melting), and this

Mantle Convection, Fig. 6 Left panel: tomographic images of slabs beneath Mexico (W. Spakman via van Keken et al. (2002)) extending into the lower mantle, in which the top frame shows the location of the profile, the next two frames show tomographic inversions for both P and

S wave travel time anomalies. Right frame: a global compilation of plate velocity vs trench length following Forsyth and Uyeda (1975), showing that the fastest plates are connected to slabs. Slabs are not only cold mantle downwellings but are also the primary driver for plate tectonics

melt reaches the surface in two types of volcanic settings: mid-ocean ridges, where tectonic plates spread apart and draw mantle up into the opening gap, and ocean-islands or hotspots, which are anomalously productive and localized volcanic features not necessarily associated with tectonic activity, Hawaii being the most conspicuous such feature. Melts coming from the mantle in this way are silica poor (relative to more silicic rocks such as granite) and largely basaltic; hence these volcanic regions are said to produce mid-ocean ridge basalts (MORB) and ocean-island basalts (OIB), respectively. These melts are in effect messengers from the mantle, and their petrological composition, bulk chemistry, and trace element chemistry are extensive areas of research (Hofmann 1997, 2003; van Keken et al. 2002; Tackley 2015). These two types of basalts have distinct features suggesting they come from parts of the mantle that have been isolated from each other for billions of years. That seismology, mineral physics, and fluid dynamics

(geodynamics) argue for a largely well-stirred mantle with whole-layer circulation creates a dichotomy between geophysical and geochemical observations. This paradox has been one of the most fervent areas of debate in mantle dynamics for the last 30–40 years.

Because MORB and OIB are both basalts and thus have similar bulk chemistry, geochemical measurements largely focus on trace elements, in particular incompatible elements, which dissolve more readily in a rock's melt phase than its solid phase; hence during partial melting incompatible elements partition toward the melt. Indeed, the trace element signature of elements, such as uranium, thorium, and helium, has demonstrated that MORB and OIB are very distinct. In particular, MORBs appear to be significantly depleted in such trace elements relative to OIB. Since such elements tend to be removed by melting, it implies that MORBs come from a region of the mantle that has already been melted and depleted of trace elements, while OIBs come from a region of the

mantle that has undergone little previous melting and depletion. This observation implies that MORBs come from an upper mantle that has been cycled repeatedly through the plate tectonic process of mid-ocean ridge melting and separation of crust (and trace elements) from mantle, in essence cleaning the MORB source. In contrast, OIB would appear to come from a part of the mantle that has seen little of this melt processing and hence would be isolated presumably at depth from the upper mantle and plate tectonic circulation.

There are other geochemical observations that argue for separated and isolated regions or reservoirs in the mantle. For example, the concentration of radioactive daughter isotopes (e.g., ^{206}Pb , which is the final product of the decay of ^{238}U) relative to the abundance of that element's dominant and primordial isotope (e.g., ^{204}Pb) is a metric for reservoir isolation from surface processing.

The relative accumulation of daughter products implies that the rock in which they reside has seen little processing or partial melting that would have cleaned out these elements after they formed. A small relative abundance of daughter isotopes means the sample has been recently processed and cleaned, and thus little time has passed in which to produce new daughter isotopes.

Indeed, many OIBs tend to show distinctly greater relative abundance of daughter products (e.g., the concentration ratio $^{206}\text{Pb}/^{204}\text{Pb}$) than do MORB for many isotopic ratios, implying some isolation of the OIB source. However, OIBs from various islands are also fairly different from each other suggesting that reservoirs isolated from the upper mantle (the presumed MORB source) are possibly also isolated from each other. Moreover, the OIB isotopic ratios have some variation, from low MORB-like values to much higher values, which indicates that there is some mixing of a "young" processed MORB source-like mantle and a more primitive, isolated one.

These isotopic ratios are also more easily interpreted for refractory daughter products since they do not tend to escape the system (also the reason they are used to radiometrically date rocks). Volatile products, especially isotopes of noble gases such as helium and argon, require different interpretations since they can readily escape the mantle and, for helium, escape the Earth. For example, MORB has a high daughter to primordial isotope ratio $^4\text{He}/^3\text{He}$ relative to many OIBs, which is opposite to the refractory ratios involving, for example, lead isotopes. This is often interpreted as a result from degassing and loss of primordial helium ^3He from the upper mantle through plate tectonic and mid-ocean ridge processing and the subsequent repopulating of helium with its radiogenic isotope ^4He (i.e., α -particles from most large element decay sequences); in contrast, an isolated lower mantle or OIB source reservoir would have undergone little loss of primordial helium thus maintaining a smaller isotopic ratio $^4\text{He}/^3\text{He}$.

The production of the argon isotope ^{40}Ar from the decay of the potassium isotope ^{40}K has two important arguments relative to mantle layering. First, the total amount of original ^{40}K in the Earth can be roughly estimated from chondritic abundances (and other arguments beyond the scope of this essay). However, the amount of ^{40}Ar it should have produced over the age of the Earth is far in excess (by a factor of 2) of the ^{40}Ar in the atmosphere, implying that much of this argon is still buried and isolated. Moreover, one can also estimate from the trace element composition of MORBs themselves that the MORB source region as it stands now would have been lacking primordial ^{40}K and even if the entire mantle were composed of this MORB source region, it would not have been able to produce even the atmospheric levels of ^{40}Ar ; this implies that the bulk of original ^{40}K was buried in a layer different and more enriched than the MORB source region, which then produced most of the ^{40}Ar , much of which is still buried in this layer.

An often quoted straw man argument for mantle layering is the heat-flow paradox. In this case, it is reasoned that if the entire mantle were composed of MORB source material with its depleted concentration of heat-producing elements (U, Th, K), then it would not be able to produce the total heat output through the top of the mantle (about 38TW). This suggests that the heat-producing elements allowing for the mantle heat output must be buried at depth. However, this makes the assumption that most heat output is from radiogenic heating, whereas possibly less than half of it is; if most heat output is from secular cooling (loss of primordial heat), then the heat-flow paradox argument is questionable. A similar but shakier argument is based on the fact that the volcanic flux of the helium isotope ^4He , which is produced from heat-producing radioactive decay of U and Th, seems to be very low relative to what would be expected given the heat that is emanating from the mantle, implying that ^4He is also buried at depth. Again, if heat output is more than 50% from secular cooling and not all from radiogenic heating, then the low flux of helium is to be expected. Even if that were not the case, mechanisms for the flux of helium are not the same as for flux of heat; i.e., heat always escapes to space eventually by convection, conduction, and even radiation, whereas helium only escapes from the mantle if it passes through narrow melting zones, which is not inevitable, and thus it can be hidden and buried almost anywhere and not only hidden at great depth.

Finally, the production of continental crust also argues for an isolated layer in the mantle. Continental crust represents an accumulated history of mantle melting, segregation of lighter components, and removal of incompatible elements to the surface. If the continental crust were removed uniformly from a whole mantle made of primordial "bulk silicate earth" (i.e., an Earth derived from chondritic material and only segregated into mantle and core), then the concentration

of incompatible elements would not have been reduced enough to produce a mantle made of MORB source material (i.e., removal of continental crust would not have depleted the whole mantle enough to make MORB source). However, if the crust were removed from 1/3 to 1/2 of the mantle, that resulting depleted portion would very closely match MORB source composition. This argues that the continental crust segregated only from the upper portion of the mantle, not the whole mantle, and thus there remains a deeper unsegregated mantle at depth (see van Keken et al. 2002; Tackley 2015).

Although there are numerous geochemical arguments for a layered mantle with an isolated and undepleted mantle at depth, they largely conflict with geophysical evidence for whole mantle convection. Mineral physics experiments suggest that the 660 km phase change boundary might provide an impediment to mantle flow but not an impermeable barrier. Seismic tomography consistently shows subducting slabs and apparently cold downwellings extending into the lower mantle (van der Hilst et al. 1997; Grand et al. 1997). Recent high-resolution images of a hot upwelling mantle plume beneath Hawaii (Wolfe et al. 2009) as well as seismic images of other plumes (Montelli et al. 2004; French and Romanowicz 2015) also suggest vertical upward transport across the 660 km boundary. Finally, geodynamical arguments against separated layers suggest that if a lower mantle held most of the mantle's heat-producing elements, it would be implausibly hot, and by heating up the bottom of the upper mantle, it would generate much bigger mantle plumes than would be observed (Tackley 2002).

The contradiction between geochemical and geophysical inference of layered vs whole mantle convection has been persistent problem in the study of the Earth's mantle. Attempts to reconcile these observations have been numerous. A reasonably popular approach has been to allow that the 660 km boundary is not a barrier to mantle flow, but that the barrier exists at greater depth. There are seismically observable layers at the bottom of the mantle (the D'' layer), which could store enriched material, although these are also so thin, they could possibly overheat (depending on the amount of radioactive heat sources stored there). As a compromise, it has been argued that the enriched mantle exists in an approximately 1000-km-thick layer at the base of the mantle (Kellogg et al. 1999), although a layer this thick has never been seismologically observed (see Fig. 7).

In the last decade, there has been mounting evidence for two large regions of chemical heterogeneity gathered into two piles on the core-mantle boundary beneath Africa and the South Pacific. These regions are detectable for their anomalously low seismic shear velocities and are termed large low-shear-velocity provinces, or LLSVPs (Garnero and McNamara 2008; Garnero et al. 2016; Hernlund and McNamara 2015). These piles arise naturally in convection models from the action of cold downwellings or subducting

slabs impinging on the core-mantle boundary and sweeping chemically dense material toward convergence points, much as how continents accumulate on the surface (McNamara and Zhong 2005; Zhong and Liu 2016). However, the source of chemically anomalous material that comprises LLSVPs remains unknown, with the main candidates being a primordial layer that formed early in the Earth's history (Lee et al. 2010) and/or accumulated pools of dense mineral phases (e.g., oceanic crustal basalt converted into eclogite) that were delivered to the bottom of the mantle through billions of years of the Earth's subduction history (Christensen and Hofmann 1994; Mulyukova et al. 2015). The isolation and longevity of these piles (e.g., Mulyukova et al. 2015) make them a viable source for isolated and semiprimitive source materials for OIB. Indeed, upwelling mantle plumes are hypothesized to initiate and emerge from the edges of these dense piles, thus supplying enriched OIB material (e.g., Hernlund and McNamara 2015; Dannberg and Gassmöller 2018). The fixity of LLSVPs for hundreds of millions of years has also been proposed as evidence that they are primordial features of the deep Earth (e.g., Conrad et al. 2013), although this interpretation remains debated (e.g., Rudolph and Zhong 2013; Zhong and Liu 2016). Nevertheless, LLSVPs are a viable source for chemical layering in the mantle that would give rise to distinct OIBs; to a large extent, they are similar to the abyssal layer predicted by Kellogg et al. (1999), albeit in a smaller and non-contiguous layer.

Other mechanisms for reconciling geochemical and geophysical observations, but not invoking layering, have been proposed as well. These mostly involve differential melting. For example, one model considers the whole mantle as a plum-pudding mix of volatile (e.g., water)-enriched plums in a depleted, drier, and harder to melt pudding. The pressure release melting in mantle plumes is stopped at higher pressures at the base of 100-km-thick lithosphere, so this could involve mostly melting of volatile-rich plums leading to an enriched OIB signature; upwelling mantle making it all the way to the surface at ridges would undergo more pressure drop and thus could also melt the drier mantle pudding, resulting in MORB that seems depleted relative to OIB (Ito and Mahoney 2005a, 2005b). Another model exploits the fact that transition zone minerals seem to be able to absorb water more readily than material above it (and below it). A transition zone with a little water will be dry relative to its solubility or water storage capacity. However upwelling material passing through the transition zone would carry this slightly damp material into the upper mantle at the 410 km boundary, and since the upper mantle olivine has poor water solubility, it would be closer to saturation and likely melt. A little melting at 410 km depth of the broad upwelling mantle (forced upward by the downward flux of slabs) passing through and out of the transition zone would cause it to be

Mantle Convection,

Fig. 7 Two end-member mantle mixing models. In the abyssal layered model (left), the source for enriched ocean island basalt (OIB) is in a deep primordial layer, while the source for depleted mid-ocean ridge basalt (MORB) is in the upper recycled mantle (after Kellogg et al. (1999)). In differential melting models, such as the water-filter model (right), the MORB and OIB sources undergo different styles of melting, but the mantle still undergoes whole-mantle circulation; see text for further explanation (after Bercovici and Karato (2003); Leahy and Bercovici (2007))

stripped of incompatible elements as it flows into the upper mantle, leaving a depleted MORB source region; because of the high pressures and high compressibility of melt, the partial melt that has cleaned this upwelling mantle would be dense and remain behind, eventually to be entrained by slab-driven downwelling back into the lower mantle. Upwelling mantle plumes, on the other hand, would go through the transition zone too fast to become hydrated and thus would undergo little melting and filtering at 410 km depths, leaving largely

enriched OIB. This model, called the transition-zone water filter (Bercovici and Karato 2003; Karato et al. 2006; Leahy and Bercovici 2010) (see Fig. 7), predicts that the 410 km should be the site of melting, and this has been borne out in various seismological studies (e.g., Revenaugh and Sipkin 1994; Song et al. 2004; Tauzin et al. 2010); however, the theory is still controversial given the state of knowledge of melt properties and their solubilities of incompatible elements at these depths and pressures (Wood and Corgne 2015).

Mantle Convection and the Generation of Plate Tectonics

The link between plate tectonics and mantle convection is one of the oldest and most challenging problems in the history of geodynamics. The original theories of mantle convection put forward by Holmes (1931) were developed in the context of explaining continental drift as articulated by Wegener (1924). Although the later theory of plate tectonics is the grand-unifying principle of geology, it is a kinematic theory in that it describes surface motions, but not their cause. Mantle convection is widely accepted to be the engine for plate motions since it is a fundamental mechanism for exploiting the energy sources of the Earth's interior, i.e., loss of primordial and radiogenic heat. It is now generally regarded that the plates themselves are a feature of mantle convection in that they are the mobile upper thermal boundary layer of convective cells that thicken as they cool in their migration away from ridges until they are heavy enough to sink along subduction zones.

One of the major accomplishments of mantle dynamics theory is that convective fluid velocities, calculated in any number of ways, consistently predict the measured scales of plate tectonic velocities, i.e., between 1 and 10 cm/yr. Such velocities were inferred even in the 1930s from both gravity and heat-flow measurements (Pekeris 1935; Hales 1936) and are well-known by the force balance on sinking slabs (e.g., Davies and Richards 1992), as well as global heat extraction from mid-mantle cooling by slabs (Bercovici 2003). Moreover, plate motions are well correlated with the presence of slab forcing, in particular that tectonic plates with a significant portion of subduction all have velocities roughly an order of magnitude faster than plates without substantial subduction zone (Forsyth and Uyeda 1975); see Fig. 6. Thus, because cold sinking slabs seem to be the major expression of convection, major driver of plate motions implies that the plates are convection (see Coltice et al. 2019).

The Plate Generation Problem

While convective forces (especially slab pull) are important for driving plate tectonics, understanding how plates self-consistently arise from mantle convection is a major goal in geodynamics. Up until the early 1990s, it was believed that since plate-like motion of the lithosphere was essentially discontinuous, it could not be predicted or reproduced by fluid dynamical convection theories. However, in the last 25 years or so, there has been major progress with fluid dynamical models yielding plate-like motion by incorporating more sophisticated rheological weakening mechanisms, such as brittle/plastic yielding or damage mechanics.

Both a clue and frustration in understanding the origin of plate tectonics are that the Earth appears to be the only known terrestrial planet that has plate tectonics (see Gregg 2015), in

addition to liquid water as well as life, which are all either causative (i.e., necessary conditions for each other) or coincidental. While our planet supports plate tectonics, our ostensible twin, Venus, does not; this remains a leading-order quandary in Earth sciences, and to solve it one must understand how and why plate tectonics is generated at all. Of course geoscience has, until the mid-1990s, only sampled the few planets of our own solar system, and thus the data was sparse; with the advent of extrasolar planet discovery (see Laughlin and Lissauer 2015), this sparseness should be mitigated, and perhaps other planets will be discovered with plate-like mantle circulation from which we will learn more about how our own planet works (e.g., Valencia et al. 2007; Korenaga 2010; van Heck and Tackley 2011; Foley et al. 2012; Tackley et al. 2013).

There are of course various qualitative and philosophical questions about how and why plate tectonics forms, evolves, and exists, but for these to be predicted or reproduced in a physical theory, one requires quantifiable questions. In short, what are the metrics of plate generation? Two fundamental features of plate-like motion exist for instantaneous motions: these are *plateness* (Weinstein and Olson 1992) and toroidal motion (e.g., Hager and O'Connell 1979; O'Connell et al. 1991; Bercovici et al. 2000, 2015). Plateness is essentially the extent to which surface motion and the strength of the lithosphere are like that for nearly rigid blocks separated by narrow or localized weak boundaries. Toroidal flow is characterized by strike-slip motion and plate spin (Fig. 8). Toroidal motion has no direct driving force in buoyant convection (which drives only vertical and divergent motion); however, it has as much energy in the present-day plate tectonic velocity field as the buoyantly driven motion (called poloidal motion). The globally averaged toroidal motion is dependent on the lithosphere's reference frame (e.g., hotspot frame), and the field in general changes through time (Cadek and Ricard 1992; Lithgow-Bertelloni et al. 1993); however, the toroidal field is a quantifiable and significant feature of global plate motions. Such measurable quantities as plateness and toroidal flow are important for testing the predictions of plate generation theories. Both phenomena rely on reasonably strong nonlinear rheological feedback effects to permit large strength variations for high plateness (i.e., rapidly deforming zones are weak, slowly deforming ones are strong), as well as coupling of buoyantly driven flow to vertical torques that drive toroidal spin and shear (Bercovici 2003; Bercovici et al. 2015).

In the last few decades, plate generation models have become increasingly sophisticated, in concert with further expansion and accessibility of high-performance computing. Instantaneous plate-like behavior has been achieved with convection models employing various forms of plastic yield and self-weakening criteria. Incorporation of these laws has led to the prediction of reasonable toroidal and poloidal flow (Bercovici 1993, 1995) and by including the rheological

Mantle Convection, Fig. 8 The horizontal divergence (which measures spreading and convergence rates) and vertical vorticity (which measures angular velocity and horizontal shear) of present-day plate motions (from Dumoulin et al. 1998), which are associated with poloidal and toroidal flow, respectively. Poloidal flow is equivalent to basic convective motion driven directly by thermal buoyancy. Although present in the Earth's plate-mantle system, toroidal flow does not arise naturally in basic viscous convection but requires the coupling of convective motion with nonlinear rheological effects

effects of melting at ridges has attained localized passive spreading zones (Tackley 2000). Models using plastic yielding have been extended to three-dimensional spherical models, creating the first global models of plate generation from mantle convection (van Heck and Tackley 2008; Foley and Becker 2009) (Fig. 9), including the effects of continents (e.g., Coltice et al. 2019).

However, models that use plastic or instantaneous self-weakening rheologies only allow weak zones to exist while being deformed, thus cannot correctly model dormant weak zones (e.g., sutures and inactive fracture zones). Rheological mechanisms that allow weakening to persist over time have also been studied. While thermal weakening is a well-understood mechanism, thermal anomalies diffuse too fast, and it is highly unlikely that, for example, sutures are thermal remnants. Weakening by hydration, or with water as a secondary phase (i.e., by providing pore pressure), is a strong candidate as well, although the mechanism for ingesting water to depth is problematic (Korenaga 2017) and requires mechanisms such as cracking enhanced by thermal stresses (Korenaga 2007).

Damage in the form of grain-size reduction (e.g., Karato et al. 1980; Braun et al. 1999; Bercovici and Ricard 2005; Austin and Evans 2007; Rozel et al. 2011) is also a strong candidate for a weakening mechanism, especially given evidence in the form of mylonites, which are small grained and highly deformed metamorphic rocks pervasive in many plate boundary environments (e.g., White et al. 1980; Jin et al. 1998; Warren and Hirth 2006; Skemer et al. 2010; Hansen et al. 2013). The coexistence of grain-size reduction with grain-size-sensitive (e.g., diffusion creep) rheology allows a positive shear-localizing feedback mechanism to generate weak plate boundaries, and its occurrence at depths where the lithosphere is strongest makes grain-size weakening particularly appealing. However, grain-size reduction and weakening in olivine (the upper mantle's primary mineral phase) tend to occur in exclusive areas of deformation space (i.e., weakening occurs during diffusion creep, while grain-size reduction occurs in dislocation creep; see De Bresser et al. (2001)), and thus a self-softening feedback by which plate boundaries form is problematic. Moreover, grain growth in olivine is possibly relatively fast (Karato 1989), which would

Mantle Convection, Fig. 9 Three-dimensional spherical shell convection with a plastic-type lithospheric rheology showing plate-like behavior. Left panel shows isothermal surfaces and in particular cold downwellings. The right panel shows surface viscosity with velocity

vectors superimposed. Note the passive divergent and rheological weak zone forming midway between the two major downwelling regions (Adapted from Foley and Becker (2009). American Geophysical Union)

promote rapid healing of weak zones. However, these problems are likely mitigated by the fact that mantle lithospheric rocks are polyminerallic, with two dominant mineral phases of olivine and pyroxene; indeed, plate boundary mylonites exhibit grain-size reduction associated with the intermixing of mineral phases (e.g., Olgaard 1990; Warren and Hirth 2006; Skemer et al. 2010; Herwegh et al. 2011; Linckens et al. 2015; Tasaka et al. 2017; Cross and Skemer 2017; Wiesman et al. 2018; Bercovici and Ricard 2016; Bercovici and Skemer 2017; Mulyukova and Bercovici 2017; Bercovici and Mulyukova 2018). Two-phase or polyminerallic grain-damage theory (Bercovici and Ricard 2012) has provided a physical framework for the formation of plate boundary weak zones based on laboratory and field studies of mylonites. A key component of the theory is that mutual Zener pinning between the mineral phases both facilitates damage and grain-size reduction while also impeding grain growth and healing. Applications of the theory have demonstrated the generation of toroidal motion and strike-slip deformation from poloidal flow (Bercovici and Ricard 2013) and facilitating the formation of subduction zones through the collapse of passive margins (Mulyukova and Bercovici 2018). Grain-damage theory has also been used to explain how Hadean proto-subduction and associated damage and weakening allowed for the accumulation and inheritance of weak zones, which permitted the emergence of global plate tectonics in the Archean Earth by approximately 3Ga (Bercovici and Ricard 2014) (Fig. 10) as hypothesized by Condie and Kröner (2008) (see also Korenaga 2013); for a review of grain-damage, applications to plate generation, and recent developments, see Mulyukova and Bercovici (2019).

Use of both plastic/brittle yielding and damage theories of plate generation has been used to elucidate the planetary dichotomy between the Earth and Venus and the causal link between climate, liquid water, and plate generation. The Earth and Venus are ostensible twins, but the Earth has plate tectonics and Venus does not. This is often attributed to lack of liquid water on Venus, which would otherwise lubricate plate motions; however, the Earth's lithosphere is likely to be no more hydrated than Venus's because of melting dehydration at ridges (Hirth and Kohlstedt 1996). Recent studies have hypothesized that the role of water in maintaining plate motion is not to lubricate plates but to be an agent for the carbon cycle, which thus allows for a temperate climate on the Earth. A cool surface on the Earth, according to one hypothesis (Lenardic et al. 2008), causes a larger temperature drop across the lithosphere than would occur on Venus (because of temperature-dependent viscosity), and thus lithospheric buoyant stresses are large enough on the Earth to induce plastic/brittle failure, but not on Venus. An alternative hypothesis (Landuyt and Bercovici 2009; Foley et al. 2012; Bercovici and Ricard 2014) states that plate-like motion depends on the competition between damage and healing (where, e.g., if lithospheric damage and weakening are due to grain-size reduction, then healing and stiffening are due to normal grain growth), where a high damage-to-healing ratio promotes plate-like motion, while a lower ratio yields stagnant-lid behavior. A cooler surface temperature inhibits healing, while a hot surface promotes healing, thus leading to plate-like behavior on a planet like the Earth with a temperate climate but not on a planet like Venus. Both hypotheses emphasize that water dictates conditions for

Mantle Convection, Fig. 10 A calculation of pressure-driven flow in a thin 2-D horizontal layer model of the lithosphere, where the pressure low is akin to a single subduction zone (see schematic frame). The rheology of the layer is governed by the grain-size evolution, damage, and pinning model of Bercovici and Ricard (2012, 2013). In this case the low pressure zone P is imposed and then rotated about a vertical axis by 90 degrees three times (with roughly 10Myrs dimensional time between rotations to develop damaged weak zones) as an idealization of intermittent and chaotic subduction during the early Archean. The bands of damage induced by flow and deformation induced by the pressure low from a previous orientation are long-lived, inherited, and amplified by

the lithospheric flow of the next orientation, resulting in localized but passive bands of strike-slip vorticity Ω and positive divergence S (red and yellow contours; convergence with $S < 0$, indicated by blue contours, is actively driven by the pressure low). Thus a complete plate arises with a contiguous weak plate boundary (indicated by viscosity $\bar{\mu}$) while only being driven by subduction, which is the final state shown (with final dimensionless time indicated on the P frame). Dimensionless extrema for contours or vectors are indicated below each frame, save P which is always between 0 and 1. This model is proposed to explain the emergence of plate tectonics in the Archean, from proto-subduction 4Ga to global tectonics by ~ 3 Ga. (Adapted from Bercovici and Ricard 2014)

plate generation by its modulation of climate and not on direct strength reduction.

Finally, subduction initiation continues to be an extremely challenging issue in geodynamics (Stern 2004; Wada and King 2015). The strength of thick cold pre-subduction lithosphere is such that it should never go unstable and sink, at least not on geological time scales (or cosmological ones either). Thus how and why subduction zones form remains enigmatic. Mechanisms range from weakening by rifting (Kemp and Stevenson 1996; Schubert and Zhang 1997), sediment loading and water injection (Regenauer-Lieb et al. 2001), reactivation of pre-existing fault-zones (Toth and Gurnis 1998; Hall et al. 2003; Lebrun et al. 2003), initiation

by mantle plumes, especially in the Archean Earth (Gerya et al. 2015), and grain evolution and damage in passive margins (Mulyukova and Bercovici 2018). That subduction on the Earth is one-sided (i.e., the lithosphere or thermal boundary layer on one side of the subduction zone sinks, not both sides as in simple convection) is also a significant mystery, although it is possibly caused by hydrous melting and weakening of the mantle wedge above the sinking slab, which inhibits entrainment of the overriding lithosphere (Gerya et al. 2008). Finally, an unresolved enigma concerns the age of subduction zones. The convective picture of plate motions would have plates subduct when they get old, cold, and heavy. However, the seafloor age distribution implies that

subduction rate is independent of plate age, such that the age of plates at subduction zones is distributed from nearly zero age (i.e., subducting ridges) to the oldest ages of roughly 200 Myrs (see Becker et al. 2009).

Summary

Mantle convection is the central theory for how the Earth works, i.e., what drives geological motions as well as the cooling history and chemical evolution of the planet. The theory is based on the simple notion that the Earth (and other terrestrial planets) must cool to space and in so doing release heat and gravitational potential energy through thermal convection. Thermal convection theory itself is a well-established physical theory rooted in classical mechanics and fluid dynamics. Much of the physics of basic convection goes far in describing circulation and structure in the Earth's mantle, for example, the flow velocities, establishment of thermal boundary layers, and even the prevalence of slab-like downwellings and plume-like upwellings. However, numerous quandaries and paradoxes persist because much remains to be understood regarding the many complexities of the exotic convecting "fluid" in the mantle. How the Earth appears to be stirred by deep subducting slabs but still appear to be unmixed when it comes up at either mid-ocean ridges or ocean islands remains a mystery, much of which is due to our incomplete understanding of the processes of melting, chemical segregation, and mixing in the mantle; however, recent progress in imaging and modeling chemically dense piles on the core-mantle boundary (LLSVPs) has advanced our understanding considerably. How and why the Earth's mantle convects in the form of plate tectonics, unlike other terrestrial planets, remains one of the biggest questions in geoscience; this problem is undoubtedly related to the mantle's exotic rheology in which flow depends on multiple properties including temperature, stress, chemistry, and mineral grain size. Recent work coupling geodynamics with rock physics and mineral grain evolution has provided fresh insight and a new theoretical framework with which to understand how tectonic plates are possibly generated. Thus, while mantle convection remains one of the grand unifying physical theories of how the Earth works, many of the major questions and mysteries about the mantle remain unsolved and are thus ripe for discovery by future generations of Earth scientists.

Mantle D'' Layer

Thorne Lay

Earth and Planetary Sciences Department, University of California, Santa Cruz, CA, USA

Definition and Introduction

Earth's lower mantle extends from the base of the transition zone (commonly assigned a depth of 660 km, corresponding to the average depth of a global seismic velocity discontinuity) to the core-mantle boundary (CMB) at a depth of ~2,900 km below the surface. This thick layer of rock comprised of silicate and oxide minerals has gradual increases with depth of P- and S-wave seismic velocities and density that are generally consistent with adiabatic self-compression of a uniform composition material over most of the depth range (see ► [“Earth's Structure, Lower Mantle”](#)). Large-scale lateral heterogeneities in the seismic velocities of about $\pm 1\%$ are apparent in the central lower mantle, and these likely involve thermal and chemical signatures of upwellings and downwellings in the slowly convecting deep mantle system (see ► [“Mantle Convection”](#)). The deepest few hundred kilometers of the lower mantle have generally reduced seismic velocity gradients, localized seismic velocity discontinuities, and strong large-scale seismic velocity heterogeneities of $\pm 2\text{--}4\%$. This portion of the lower mantle is called the D'' layer (or, more commonly, the D'' region, because the onset of anomalous properties varies significantly in height above the CMB from place to place) in recognition of its distinctive properties relative to the shallower lower mantle (D' layer). Localized regions of extreme (10–30%) seismic velocity reductions in thin layers or lumps only tens of kilometers thick are found at the base of D''. The structural

heterogeneities in the D'' region are usually interpreted as manifestations of complex thermal and chemical boundary layers at the CMB, to some extent mirroring the structural heterogeneities found in the near-surface lithospheric boundary layers. The structure and dynamics of the D'' region are believed to be of fundamental importance to the mantle and core dynamical systems, prompting many seismological, geodynamical, and mineral physics investigations of D'' properties.

The D'' region may have distinct bulk composition from the rest of the lower mantle, involving residues from deep mantle melting, core formation, chemical reactions between the core and mantle, or dynamical segregation of materials over time, but this possibility has to be assessed in the context of expected behavior of major lower-mantle minerals for the extreme pressure-temperature (P-T) conditions near the CMB. The primary minerals in the lower mantle are thought to be $(\text{Mg}_x\text{Fe}_{1-x})\text{SiO}_3$ perovskite, $(\text{Mg}_x\text{Fe}_{1-x})\text{O}$ ferropericlasite, and smaller amounts of CaSiO_3 perovskite and high-pressure forms of SiO_2 (see ► [“Earth’s Structure, Lower Mantle”](#)). The relative amount of Mg versus Fe, given by x , is ~ 0.9 , but the properties of the minor Fe component are being intensely investigated because transitions from high-spin to low-spin in Fe^{3+} and Fe^{2+} are expected in lower mantle perovskite and ferropericlasite as pressure increases, with strong effects on chemical and transport properties of the material in the deep mantle. Some Al may substitute in both the Mg and Si sites in the Mg-perovskite. Mg-perovskite comprises as much as 70% of the lower mantle, making it the most abundant mineral in the Earth. A phase change in Mg-perovskite, discovered in 2004, occurs under P-T conditions existing a few hundred kilometers above the CMB, likely giving rise to some of the complexities of the D'' region (Hirose and Lay 2008). Mineralogical complexity of D'' is expected to be enhanced relative to the bulk of the lower mantle due to proximity to huge contrasts in composition and physical properties across the CMB.

The CMB separates the solid silicate- and oxide mineral mantle from the molten metallic-alloy outer core. The density increases from about $5,500 \text{ kg/m}^3$ to $9,900 \text{ kg/m}^3$ across the CMB, and the viscosity decreases by many orders of magnitude. These contrasts maintain a very sharp boundary and result in thermal and chemical boundary layers in both D'' and the outermost core, although any core structures may be very thin and hard to detect (see ► [“Earth’s Structure, Core”](#)). With any mass flux across the CMB being constrained to involve chemical diffusion, heat transports across the CMB by conduction from the hot core into the lower-temperature mantle. The temperature drop across the resulting CMB thermal boundary layer is estimated to be in the range $1,000\text{--}2,000^\circ\text{C}$, and there is a heat flow of $5\text{--}15 \text{ TW}$ across the boundary (the heat flow through Earth’s surface is $\sim 46 \text{ TW}$) (Lay et al. 2008). Over time, relatively dense

materials in the mantle (for example, any basaltic component in subducted slabs that penetrate into the lower mantle) are likely to have concentrated in D'', while light dross, expelled from the core may have accumulated on the underside of the CMB. Thermo-mechanical and electromagnetic interactions across the CMB couple the mantle and core dynamical systems, and this influences the geodynamo (see ► [“Core-Mantle Coupling”](#)). The D'' region is relatively accessible to seismic imaging, and its inferred structural and dynamical properties are discussed here. Trønnes (2009), Garnero and McNamara (2008), Lay (2007), and many papers in Hirose et al. (2007) provide technical reviews of ongoing research topics and conceptual models for structures and processes occurring in D''.

Seismic Velocity Models for D''

Seismology provides the highest resolution of D'' elastic material properties because it is possible to decipher seismic wave interactions with the lowermost mantle and CMB in recordings of ground shaking at seismic stations around the world. Seismic wave observations can resolve D'' region P- and S-wave velocities, reflections from sharp velocity jumps, shear-wave splitting caused by anisotropy of the elastic structure, and scattering properties. One-dimensional (1D) depth-varying seismic velocity models, such as the Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981), usually have reduced velocity gradients in the deepest $\sim 150 \text{ km}$ of the mantle, representing the global departure of D'' velocity structure from that of the overlying lower mantle. Efforts were initially made to interpret the low (or even negative) velocity gradients in such laterally averaged models of D'' structure as the result of a superadiabatic temperature increase across the CMB thermal boundary layer; strong temperature increases are required to account for seismic velocity reductions due to the low thermal expansion coefficient of deep mantle rock under high pressures. However, it is now clear that there is no meaningful “average” 1D structure for the D'' region useful for a robust interpretation of the boundary layer. It is more useful to discuss the seismic properties of D'' by emphasizing the lateral variations in structure, as is also the case for the lithosphere.

Seismic tomography has been applied to develop three-dimensional (3D) seismic velocity models for the entire mantle for over 30 years. This method extracts 3D P-wave and S-wave velocity fluctuations relative to 1D reference models by inversion of massive data sets with crossing ray paths for which seismic wave travel times are measured. 3D velocity inversions indicate that seismic velocity heterogeneity in the mid-lower mantle is relatively weak, but that in the lowermost $300\text{--}500 \text{ km}$ of the mantle heterogeneity increases with depth, becoming stronger in D'' than anywhere else in the

Earth except for the uppermost mantle where major thermal, chemical and partially molten heterogeneities are known to exist.

An unanticipated aspect of the D'' seismic velocity heterogeneity revealed by seismic tomography is that it is dominated by large-scale patterns, with huge continuous volumes of high or low-seismic-velocity material having scale-lengths of hundreds to thousands of kilometers. This predominance of large-scale variations is observed in both P-wave and S-wave velocities, with relatively high-velocity regions of D'' underlying the circum-Pacific margins and two nearly antipodal regions of pronounced low S-wave velocity beneath the southern central Pacific and southern Africa/southern Atlantic/southern Indian Ocean (Fig. 1a). High-seismic-velocity regions are likely to have lower temperature than low-seismic-velocity regions, although chemical differences and phase changes may contribute to the variations. Recent global tomographic models have $\pm 4\%$ S-wave velocity variations in D'', two or three times stronger than those found in the mid-lower mantle, and comparable to the $\pm 5\text{--}8\%$ variations at depths near 150 km in the upper mantle. While mid-mantle variations tend to have more spatially concentrated heterogeneities, there is a significant degree of radial continuity of high- and low-velocity anomaly patterns throughout the lower mantle, possibly linking subduction zones at the surface to high-velocity regions in D'' and hot-spot locations at the surface to low-velocity regions in D'' (Garnero and McNamara 2008).

P-wave velocity variations in current tomographic models have $\pm 1.0\text{--}1.5\%$ fluctuations, with low-velocity areas beneath the southern Pacific and south Atlantic/Africa and high velocities under eastern Eurasia. There is not as strong of an increase in P-wave velocity heterogeneity in D'' relative to that in the overlying mantle as there is for S-wave velocity, which can be partially attributed to the expected greater sensitivity of S-wave velocity to temperature variations in a thermal boundary layer. There is a large-scale spatial correlation between S- and P-wave velocity patterns, as expected for temperature-induced variations, but in some regions, such as beneath the northern Pacific, this correlation breaks down. In other regions, such as beneath the central Pacific, the S-wave variations are much stronger than the P-wave variations even though both have the same sign. The decorrelation of the seismic velocities and the variation in their relative strengths provide strong evidence that thermal variations alone cannot explain the large-scale patterns of seismic velocity heterogeneity; so there is likely to be chemical heterogeneity present in D'' (Trampert et al. 2004). It is important to recognize that tomography patterns are relative to the global average velocities at D'' depths, and that these averages do not necessarily define "normal" mantle structure. This results in uncertainty in interpretations of the velocity fluctuations (for example, high velocity regions may be anomalously low temperature,

perhaps due to cool downwellings that have disrupted an overall hot boundary layer, or low-velocity regions may be anomalously hot regions, perhaps partially melted, within a chemically distinct, high velocity layer). Resolution of finer scale seismic properties in D'' is pursued in order to overcome this ambiguity in interpreting global seismic tomography images.

Seismic Velocity Discontinuities in D''

Rapid P-wave and S-wave velocity increases and/or decreases are observed several hundred kilometers above the CMB in many regions (Lay and Garnero 2007), and are sometimes used to define the top of D''. The most prominent structure is a rapid shear velocity increase of 1.5–3% 150–350 km above the CMB found over intermediate-scale (500–1,000 km) regions beneath circum-Pacific margins and some other locations (Fig. 1a). The increase in velocity may be distributed over a few tens of kilometers or it may be very abrupt (a "discontinuity") (Lay 2008), and in some regions it can vary in depth by as much as 100 km over lateral scales of just 200 km. The velocity increase is required to account for observed S-wave reflections that arrive before reflections from the CMB. Similar structures have been found in localized regions for P-waves, usually with a smaller velocity increase of 0.5–1.0%, but in some regions there is a P-wave velocity decrease at the same depth as an S-wave increase (Hutko et al. 2008). Lay and Garnero (2007) review many observations and models for this D'' seismic velocity discontinuity.

The D'' S-wave velocity discontinuity is commonly observed in regions with large volumes of high S-wave velocity material in D'', indicating that it is associated with relatively low temperature environments. An abrupt increase in velocity with depth is not expected for a thermal boundary layer structure, so most interpretations of this correlation invoke the notion of localized ponding of cool subducted lithospheric slabs that have sunk to the lowermost mantle, retaining enough thermal and chemical anomaly to account for the high seismic velocity. However, it is not clear that slab thermal and compositional anomalies can account for a sharp reflecting structure, so additional presence of a phase change may be required. Alternatively, chemically distinct high velocity material may be present in these regions, perhaps involving ancient accumulated material concentrated during core formation or segregated oceanic crustal materials that have accumulated over Earth history. Observations of an S-wave velocity increase beneath the central Pacific, a relatively low velocity region far from any historical subduction zone, complicates any attempt to interpret the velocity discontinuity solely as the result of recent slab thermal anomalies (Lay and Garnero 2007).

Mantle D'' Layer, Fig. 1 (a) Schematic cross-section through the Earth indicating large structures in the D'' region (below the red dashed line) above the core-mantle boundary (CMB) (adapted from Trønnes 2009). The two large low shear velocity provinces (LLSVPs) under Africa and the Pacific are indicated, with thin ultra-low velocity zones (ULVZs) at their base and margins. Areas of upwelling warm mantle surround and overlie the LLSVPs. Areas of relatively cool mantle downwellings are underlain by D'' material with post-perovskite (ppv) occurrence. Detailed seismic S-wave velocity models from both an LLSVP margin and a down-welling region are shown on the right, with the D'' velocity

discontinuity seen at depths of 2,600–2,650 km. Both regions have a deeper velocity decrease that may represent conversion from post-perovskite back to perovskite (pv) in the steep thermal gradient above the CMB at 2,891 km depth. (b) S-wave and P-wave velocity models from areas of intense ULVZ under the central Pacific, showing strong velocity reductions below low velocity (LLSVP) regions. (c) Representative anisotropic S-wave velocity models, indicating high Vsh velocities below circum-Pacific regions with strong D'' discontinuities and high Vsv velocities in LLSVP environments

Post-perovskite in D''

The major seismic velocity discontinuities in the transition zone are generally attributed to phase changes in upper mantle minerals that cause abrupt changes in density and elastic wave

velocities. The experimental discovery of a phase transition in MgSiO_3 perovskite (Murakami et al. 2004) for P-T conditions near the top of D'' may provide a corresponding explanation for the D'' S-wave velocity discontinuity. The high-pressure polymorph is called post-perovskite, and laboratory and

theoretical predictions of its properties indicate that it should have 1–2% higher S-wave velocity, little, or no change in P-wave velocity, and 1–1.5% higher density than perovskite, which can account for some of the seismological complexities of D'' (Hirose et al. 2007). Presence of Fe and Al in the perovskite cause the phase transition to occur over a pressure range rather than at a single pressure for a given temperature, and this may be difficult to reconcile with an efficient seismic wave reflector. The perovskite-to-post-perovskite transition occurs at lower pressure for lower temperatures, thus lateral temperature variations in a thermal boundary layer are expected to modulate the depth of the transition. If the phase transition occurs in a relatively cool region of accumulated downwelling slab material, the discontinuity should be higher above the CMB than in warmer areas of D'' with the same composition. Some calculations indicate that the pressure of the transition may decrease if Fe is present in the perovskite, thus chemical heterogeneity could also modulate the depth of the phase transition.

The P-T behavior of the post-perovskite phase change tends to enhance thermal instabilities within the thermal boundary layer, but its thermal transport properties are still uncertain due to the possibility of Fe high-spin to low-spin transition and the lack of constraint on Fe partitioning coefficients between post-perovskite and ferropericlase. One of the most important attributes of the phase transition is that it can provide an absolute temperature tie-point for D'', if an observed S-wave reflector at a specific depth (hence, pressure) is correctly attributed to the phase change and if the P-T-X behavior (where X indicates precise mineralogical composition) of the phase change is experimentally and theoretically constrained. This is important because estimates of temperature structure in the lowermost mantle and outermost core are largely based on extrapolations over tremendous depth ranges of laboratory-estimated-temperature tie-points for the olivine-spinel phase transition near 410-km depth and the iron alloy solidus at the 5,150-km deep inner core-outer core boundary.

Laboratory measurements indicate that the temperature at a depth of about 2,600 km is close to 2,500 K, if the D'' discontinuity is caused by transition to post-perovskite. With an estimated outermost core temperature of 3,500–4,000 K, this favors a 1,000–1,500° increase in temperature across the D'' thermal boundary layer. Such a strong temperature increase could cause a reversion from post-perovskite to perovskite to take place in the hottest region right above the CMB, and some evidence for such a second crossing of the phase boundary has been inferred from seismic observations of a S-wave velocity decrease 50–100 km above the CMB (Fig. 1a; Lay et al. 2006; van der Hilst et al. 2007). The effects of the phase transition on seismic velocities must be considered when inferring lateral temperature structure in D'' from seismic velocity variations, given that the volume of the high

S-wave velocity post-perovskite material should vary laterally in either a depth-modulated layer or a “lens,” depending on stability of post-perovskite right at the CMB.

Large Low Shear Velocity Provinces in D''

The two large antipodal regions with low S-wave velocity appear to be chemically distinct regions of D'' (Fig. 1a). The margins of these large low shear velocity provinces (LLSVPs) have abrupt steep-walled lateral gradients, over scales of tens of kilometers, which indicates a chemical change relative to surrounding D'' material rather than just a thermal change. The region beneath the southern Atlantic and Africa has been modeled as having margins with an abrupt –1 to –3% S-wave velocity decrease 250–300 km above the CMB (shallowing to ~800 km above the CMB under Africa), with average velocities in D'' that are 3–5% lower than for PREM (e.g., Wang and Wen 2006). The sub-Pacific LLSVP has comparable velocity contrasts and varying vertical extent, and may be two separate mounds of material that extend upward into the central lower mantle. P-wave velocity tends to be slightly low in the LLSVPs, but less than what would be expected if the S-wave velocity reductions were entirely caused by high temperatures. Thus, there is an anomalously high incompressibility in the LLSVPs, which also favors distinct chemistry. While limited in resolution, free oscillation measurements suggest that the LLSVPs are relatively high density, adding to the evidence for chemical inhomogeneity, and suggesting that these are not buoyant ‘superplumes’ as some researchers have suggested. Internal structure of LLSVPs has been detected in the form of localized velocity discontinuities (Fig. 1a) and the presence of underlying ultra-low velocity zones (see below). The velocity discontinuities may represent chemical heterogeneity or possibly post-perovskite phase transition in material with distinct Fe and Al content from surrounding high seismic velocity areas of D''.

The current position of the LLSVPs can be attributed to accumulation of chemically distinct, relatively dense material in D'' that has been displaced away from circum-Pacific areas of downwelling slab materials over the past several hundred million years (Garnero and McNamara 2008). Thermal calculations indicate that any dense chemical piles in a convecting mantle will be relatively hot as a result of inefficient heat loss, so LLSVPs would likely have combined effects of high incompressibility, high temperature, and high density. This predicts complex dynamical behavior, but the presence of the structures in D'' at this point in Earth's evolution suggests that the features are long-lived and are either remnants of much larger chemical anomalies that have slowly been entrained by mantle flow or they are being regenerated by ongoing chemical

differentiation. Aggregation of basaltic (ocean crust) components of subducted slabs is one possible mechanism for accumulation of chemically distinct material that may be sustaining the LLSVPs. The total volume of LLSVP material is several percent of the mantle, so these are significant chemical reservoirs. The possibility that the LLSVPs have been close to their present locations for hundreds of millions of years is supported by the fact that reconstructed emplacement locations of many Large Igneous Provinces (LIPs) overlie margins of the LLSVPs (Torsvik et al. 2006). If plume upwellings rise from the lateral margins of the dense piles, as suggested by numerous dynamical models, this association may be understood as a first order impact of D'' structure on geological processes at Earth's surface.

Ultra-Low Velocity Zones in D''

Thin layers or mounds of material with very strong seismic velocity reductions have been detected in D'' just above the CMB (Fig. 1b), and these are called ultralow velocity zones (ULVZs). P- and S-wave velocity models for ULVZ may have a thin layer or mound of 10–40 km thick and from hundreds to thousands of kilometers across with P-wave velocity reductions of –4 to –10% and S-wave velocity reductions of –8 to –30% (Thorne and Garnero 2004). These structures are commonly found near the margins of LLSVPs (Fig. 1a), but also occur in localized regions elsewhere. They are detected in seismic waves that reflect from or graze along the CMB.

The magnitude of the velocity reductions in the ULVZs and the factor of 2–3 ratio of S-wave velocity/P-wave velocity decrement require either the presence of a melt component or very strong chemical contrast. The temperature in the D'' thermal boundary layer will reach a peak right at the CMB (which is nearly isothermal due to the rapid convective flow occurring in the core); so ULVZs are intrinsically the hottest regions in the mantle. However, they are not globally detectable (a very thin layer < ~1 km could be present everywhere without being resolved by seismic data); so a combination of partial melting and chemical heterogeneity is implied by the patchy nature of the thicker regions of ULVZ. Seismic data indicate that the ULVZ material may be ~10% denser than surrounding D'' material, favoring high Fe content, which would contribute to the strong seismic wave velocity reductions. ULVZ affiliation with LLSVP margins may be associated with thermal convection in the LLSVPs, along with interactions with flow in the surrounding mantle (Garnero and McNamara 2008). It is not yet clear how to account for ULVZ chemical evolution, but one possibility is that they are the residue of a much more extensive lower mantle magma ocean which has largely solidified (Labrosse et al. 2007).

Seismic Velocity Anisotropy in D''

The seismic velocity structure in D'' is more anisotropic than the shallower lower mantle, with seismic velocities being dependent on the direction of propagation and the polarization of ground shaking. This results in shear-wave splitting, involving an S-wave separating into two-components with orthogonal polarization, one traveling slightly faster than the other while in the D'' region. By measuring the polarizations and travel time difference between the fast and slow S-waves, it is possible to determine the anisotropic characteristics of the medium. For most S-wave phases with ray paths grazing horizontally through the D'' region, the data can be explained by models in which horizontally polarized (SH) vibrations travel with 1–3% higher velocities (V_{sh}) than vertically polarized (SV) vibrations (Fig. 1c). This behavior is consistent with the medium having vertical transverse isotropy (VTI), which can result from hexagonally symmetric minerals with vertically oriented symmetry axes or from stacks of thin horizontal layers with periodic velocity fluctuations. The regions with the best documented cases for strong VTI in D'' tend to have higher than average S-wave velocities and strong D'' discontinuities (Fig. 1c). There are observations favoring slightly tilted (non-vertical) transverse isotropy (Maupin et al. 2005), which results in weak coupling of the SH and SV signals (the fast wave is still close to the SH polarization), as well as limited regions where SV signals are found to propagate with higher velocities (V_{sv}) than SH signals (such as in the central Pacific LLSVP, Fig. 1c).

Anisotropy in D'' is likely to be caused by either lattice-preferred orientation (LPO) or shape-preferred orientation (SPO). LPO can arise when minerals systematically orient within a flowing medium. This may exist in D'' if dislocation creep occurs, which requires relatively high stresses and low temperatures as might be found near slab downwellings. Ferropericlase has been shown to be a viable candidate for development of LPO in horizontal shear flows above the CMB, if suitable temperatures and stresses are present. It is also possible that certain slip systems can be activated such that post-perovskite can account for shear-wave splitting observed in some regions. If a region of D'' is too warm for dislocation creep, deformation will occur by diffusion processes and seismic anisotropy is only viable if heterogeneities (either chemical blobs or pockets of partial melt) are systematically aligned with the flow. Transitions from horizontal to vertical flows may account for SPO transitions from VTI to horizontal transverse isotropy, which can have V_{sv} higher than V_{sh} . Efforts continue to improve the characterization of D'' anisotropy because it has the potential to reveal ongoing deformation processes occurring in the boundary layer.

Summary

The diverse seismic properties of the D'' region appear to demonstrate the presence of heterogeneity at the base of the mantle associated with thermal and chemical boundary layers of a complex dynamical system. There is a predominance of large-scale structures in D'', and the strength of heterogeneities at intermediate and large-scales appears to be significantly greater than in the overlying lower mantle. Large low shear velocity provinces (LLSVPs), ultra-low velocity zones (ULVZs), multiple seismic discontinuities, a major phase change, and seismic anisotropy are all fundamental attributes of the D'' region. The present day configuration of D'' structures represents a "snap-shot" of an evolving system, with some aspects reflecting very long time-scale processes (LLSVPs may have been in place for at least hundreds of millions of years; ULVZs may be the last remnant of an extensive magma ocean that dates back to core formation) and much shorter time scales (post-perovskite lenses may be found in recently downwelled slab materials and seismic anisotropy may be sustained by present day dynamic shear flows). Together with the ongoing role of D'' as a thermal boundary layer that regulates cooling of the core and as the site of electromagnetic-mechanical coupling of rotation between the core and mantle, the significance of this region for Earth dynamics appears more evident than ever. While debate continues regarding the extent to which mantle material is fluxing between the shallow and deep mantle, evidence has grown to support a significant feed-back/control of D'' structures on geological processes at Earth's surface.

Definition

Mantle plume	The mechanism of up-welling of buoyant mantle material through a quasi-cylindrical structure for the formation of large igneous
--------------	---

	provinces, linear aseismic ridges, plateaus and islands on surface of the Earth.
Hotspot	Place of anomalous volcanism compared with the surrounding mantle; the process melts the mantle rocks into magma. The anomalous hot places inside the mantle have expression of active volcanism on Earth's surface.
Spreading ridge system	An underwater continuous mountainous feature lies at divergent plate boundary, where new magmatic material upwells, leading to growth of the plates on either side.

Spreading Ridge System

The rigid outer shell of the Earth is divided into a number of tectonic plates. Presently, the Earth consists of a total of 52 plates, in which 14 are large plates, viz., Africa, Antarctica, Arabia, Australia, Caribbean, Cocos, Eurasia, India, Juan de Fuca, Nazca, North America, Pacific, Philippine Sea, and

South America, and 38 are small plates (Bird 2003). The tectonic plates are bounded by one or more of the three main types of plate boundaries: (1) spreading ridges, (2) subduction zones/trenches, and (3) transform faults (Fig. 1). Plate boundaries are narrow deforming zones, characterized by significant seismicity, whereas the plate's interiors are relatively stable.

The tectonic plates are in continuous motion at a speed of up to a few centimeters per year. Each plate is in relative motion with respect to each other on the surface of the Earth. The relative motion produces new crust at spreading ridges and consumes old crust at subduction zones. Apart from these tectonic processes, plates do undergo break-ups and unifications through geologic time.

The spreading ridge, a divergent tectonic boundary between two lithospheric plates, connects with other spreading ridge system and encircles the world's oceans with a total length of about 63,000 km as a single global entity (Fig. 1). Details of all spreading ridge systems of the world oceans are placed in Table 1 for the purpose of keeping succinct

Mantle Plume: Spreading Ridge Interactions, Fig. 1 General physiographic map of the world oceans, depicting the spreading ridge systems along with major transform faults, fracture zones and subduction zones. The acronyms assigned for all ridge systems are detailed. AAR, American–Antarctic Ridge; ASC, Azores Spreading Centre; CaR, Carlsberg Ridge; ChR, Chile Rise; CIR, Central Indian Ridge; CN,

Cocos–Nazca Spreading Centre; EPR, East Pacific Rise (north and south); Ex, Explorer Ridge; GA, Gulf of Aden; GoR, Gorda Ridge; GaR, Gakkel Ridge; JF, Juan de Fuca Ridge; KR, Kolbeinsey Ridge; MAR, Mid-Atlantic Ridge (north and south); MR, Mohs Ridge; PAR, Pacific–Antarctic Ridge; RR, Reykjanes Ridge; RS, Red Sea; SEIR, Southeast Indian Ridge; SWIR, Southwest Indian Ridge

Total length of global mid-oceanic ridge systems ~ 63,000 km

information at one place. Many of the major oceanic ridge systems have been reorganized several times in the geological past that led to unification or split of the tectonic plates. One of the well-mapped ancient oceanic ridges in the Indian Ocean is the Wharton Ridge, once separated the Indian and Australian plates, and the ridge cessation at about 42 million years ago led to unification of both the aforesaid plates into a single Indo-Australian plate (Liu et al. 1983; Krishna et al. 1995, 2012).

Mantle Plume

Mantle plume is a quasi-cylindrical pipe-like structure, through which concentrated hot mantle material up-wells to the surface of the Earth. The classical hotspot model proposed by Wilson (1963) and Morgan (1971, 1972) considers the presence of magma source deep in the mantle,

therefore the chemical signatures of rising magma are distinct from those of spreading ridges. Numerous experiments have demonstrated that the plumes initiate with a leading plume head followed by a narrow conduit or plume tail connecting the plume head to the source region (Turcotte and Schubert 2002). For example, the Reunion hotspot in Indian Ocean region emplaced the Deccan flood basalts (in the form of Large Igneous Province) on western Indian Shield as a plume head (White and McKenzie 1989), Chagos-Laccadive Ridge as a plume tail, and the Reunion Island as a plume source location (Fig. 2). Initial plume volcanism is generally much more voluminous than the following volcanism in oceanic regions. In many cases, hotspots lie at the end of well-defined linear volcanic ridges, known as hotspot tracks. For example, the hotspot track associated with the Hawaiian hotspot volcanism is the Hawaiian – Emperor island – seamount chain that runs from north part of the Pacific plate to the Aleutian Islands.

Plate names: AF, African Plate; AN, Antarctic Plate; AU, Australian Plate; EU, Eurasian Plate; NA, North American Plate; NZ, Nazca Plate; PA, Pacific Plate; SA, South American Plate; SKP, Southern Kerguelen Plateau; Hotspots positions are considered from Courtillot et al. (2003)

et al. 2002). Further, the Indian Ocean ridge systems had experienced absolute motions because of specific tectonic setting of the Antarctic plate circuit (Krishna et al. 2012).

During the volcanic emplacement, the Kerguelen mantle plume had interacted in various settings with the spreading segments of the Wharton Ridge system.

Mantle Plume: Spreading Ridge Interactions, Fig. 3 Sketch diagrams showing various dynamic settings held between the Kerguelen mantle plume and Wharton spreading centers. (After Krishna et al. 2012)

We discuss various models of interactive processes held between the Wharton spreading center and Kerguelen hotspot during the formation of the NER (Krishna et al. 1995, 1999, 2012). Initially, the hotspot was placed beneath the Indian plate, which is now located in the Bay of Bengal region, possibly at some distance from the spreading center, resulting in intraplate volcanism on the Indian plate, forming the volcanic trace approximately 1500 km distance (Fig. 3a). This model is supported by the presence of regional flexure beneath the northern part of the NER (Gopala Rao et al. 1997; Krishna et al. 2009; Sreejith and Krishna 2013). Subsequently, northward migration (absolute motion) of the Wharton spreading ridge system allowed its spreading center to coincide with the hotspot for on-axis hotspot volcanism (Fig. 3b), which may have emplaced sections of the NER simultaneously on both plates. Further northward spreading center migration placed the hotspot beneath the Antarctic plate for near-ridge or ridge-flank volcanism (Fig. 3c). Evidence of Kerguelen hotspot volcanism on Antarctic plate during the formation of the NER comes from the presence of 68 Ma ages basalts from Skiff Bank, part of the Kerguelen Plateau (Coffin et al. 2002).

With continued Wharton spreading ridge migration, the hotspot moved farther from the spreading ridge beneath the Antarctic plate. As the overlying crust was rigid, the hotspot material flowed along the base of the lithosphere to reach the spreading center for on-axis volcanism (Fig. 3d), even when the hotspot was not located in the vicinity of the spreading ridge crest. The stress field created by the hotspot may have caused uplift and weakening of the overlying oceanic lithosphere, resulting in the initiation of rifting and spreading within the Antarctic plate and leading to southward ridge jumps. The continuous process of hotspot-spreading ridge interactions may have provided necessary conditions to cause multiple ridge jumps. Observations of ridge-hotspot interactions at other locations led several researchers (Brozena and White 1990; Small 1995; Hardarson et al. 1997; Mittelstaedt et al. 2011) to conclude that ridge segments jump repeatedly toward a hotspot, even when the overall motion of the ridge may be away from the hotspot.

The Azores hotspot represented by a 200-km broad thermal anomaly and its interaction with the mid-Atlantic ridge system for four different phases are discussed (Fig. 4). The gradual migration of ridge system together with the African

Mantle Plume: Spreading Ridge Interactions, Fig. 4 The proximity of Azores hotspot and its interaction with the mid-Atlantic ridge system for the ages 48 Ma, 20 Ma, 7 Ma, and Present are shown. The

hotspot shown with a red color circle is represented by a 200-km broad thermal anomaly (McNutt et al. 1989; Wolfe et al. 1997). (The Figure is adopted from Gente et al. (2003))

plate at a rate of 13 km/Myr in SSE direction resulted in northward shift of interactive area of two melt zones during the last 48 Myr (Gente et al. 2003). The coupled melt zones, even the ridge axis is 300 km away from the hotspot location, have produced abundant volcanism, and led to emplace twice thicker oceanic crust than normal crust. The rock samples collected from shallow seafloor areas of melt zones display flat to enriched light rare earth elements signature reflecting heterogeneous mantle (Schilling et al. 1977), and well supports the ridge-hotspot interaction along the mid-Atlantic ridge system.

Crustal Structure Beneath the Spreading Ridge, Volcanic Ridge and on-Spreading-Axis Hotspot Setting

The geometry of crustal structures beneath the spreading ridge system and volcanic chain when the hotspot volcanism was in intraplate or interplate positions varies significantly. An outline of seismic structure beneath the East Pacific Rise is developed following the seismic reflection results across the Rise (Detrick et al. 1987). The structure consists of layer 2 with pillow lavas and dykes, layer 3 with gabbro cumulates, axial magma chamber with low-velocity zone on its roof beneath the ridge axis, and discontinued Moho boundary beneath the magma chamber (Fig. 5a). This is a typical structure generally found beneath the spreading ridge systems of the planet Earth. Under some spreading ridge segments, the axial magma chambers are either small or absent altogether. For example, multichannel reflection experiments carried out on the Mid-Atlantic Ridge (Detrick et al. 1990) did not find evidences for presence of such intracrustal reflections associated with an axial magma chamber.

The crustal structure of the Hawaiian Islands in the central Pacific Ocean is most credible example for a

volcanic chain built by a mantle plume activity at some distance from the spreading center (Watts and ten Brink 1989). The oceanic crust with a typical thickness of about 6 km is flexed downward with addition of extra material to the top and base of the flexed crust (Fig. 5b). Watts and ten Brink (1989) opined that the extra materials seem to have been added to the flexed crust during or following the late stages of volcanic activity. The structural model suggests that the surface loading has produced the flexure to the oceanic crust, while the deep magmatic body serves as an upward subsurface load reduced the flexure to some degree. Similar kind of large crustal thickness models are also found beneath the Ori and Tamu Massifs of the Shatsky Rise oceanic plateau, northwest Pacific Ocean (Huang et al. 2018; Sager et al. 2019), but they were evolved by massive eruptions at mid-ocean ridge with extra ordinary mantle melting, which are different from the process of plume – spreading ridge interactions.

The structural model of the Ninetyeast Ridge in the eastern Indian Ocean derived from seismic and gravity results presents an explicit geological process that underwent when the Kerguelen plume was situated right beneath the spreading center of the Wharton Ridge system (Krishna et al. 2001). The impact of surface and subsurface loads on juvenile oceanic crust significantly differs from the one associated with the off-spreading-axis volcanism (Fig. 5b, c). The flexure of the oceanic crust due to surface load is very minimal, whereas the subsurface load engulfs the lower part of the crust leading to the presence of large volume of magmatic rocks beneath the Ninetyeast Ridge.

The Iceland hotspot with ridge-centered plume in North Atlantic Ocean is a classical live example on the Earth for plume-spreading ridge interactions. The crustal structure exactly beneath the location of the Iceland hotspot, where plume-ridge interactions are continuing, shows the thickness

Mantle Plume: Spreading Ridge Interactions, Fig. 5 Crustal structure beneath the spreading ridge (East Pacific Rise) (after Detrick et al. 1987), aseismic ridge (Hawaiian-Emperor seamount chain) (after Watts

and ten Brink 1989) and intersected location of mantle plume – spreading ridge (Ninetyeast Ridge). (After Krishna et al. 2001)

of 25–30 km crust with extrusive formations in upper crust and intrusive formations in the lower crust (Kumar et al. 2007; Bjarnason 2008). The Moho boundary beneath the present location of the Iceland hotspot found to be normal and sharper (Kumar et al. 2007).

Summary

The spreading ridge, an underwater mountainous feature, extends for a length of about 63,000 km as a single continuous entity in the global oceans. It is a window to the Earth's interior, through which magma continuously up-wells, and drives the tectonic plates on either side in order to accommodate newly accreted crust. Another important dynamic

process the planet Earth experiences is mantle plume volcanism. The mechanism up-wells the deep hot mantle material to surface of the Earth for formation of large igneous provinces, linear aseismic ridges, plateaus and islands. The planet Earth presently possesses about 49 hotspots and their exterior emplacements occupy an area of 11–42% of the total Earth's surface. During the ocean expansions, the hotspots sometime or other have come close to the vicinity of spreading segments of the ridge systems due to hotspot migrations and/or absolute plate motions, leading to interactive processes between them. The mechanism of formation of internal materials and geophysical and geochemical signatures of the volcanic chains greatly vary depending upon the proximity of hotspot with spreading centers of the ridge system.

Definition

Mantle plumes Localized upwelling currents of solid rock that are hotter, thus less dense, than the surrounding mantle.

Hotspots

Plate tectonics provides a framework for interpreting volcanism at plate boundaries, namely, along spreading ridges (divergent boundaries) and subduction zones (convergent boundaries). However, it does not explain intraplate volcanism, such as Hawaii, nor the excess volcanism along certain sectors of a spreading ridge, as observed in Iceland. In these regions, called hot spots, the volcanic activity can last more than a hundred million years, as indicated by the resulting age-progressive volcanic chain formed during the hotspot's lifetime. For example, the 6,000 km-long Hawaiian-Emperor volcanic chain (Fig. 1) is an alignment of roughly 100 volcanoes of progressively increasing ages. The volcanic chain was created during the last 80 Ma, as the Pacific plate drifted over the Hawaiian hot spot. The vigorous and long-lasting Hawaiian volcanism readily captured the interest of geophysicists: Tuzo Wilson (1963) proposed that the Hawaiian chain was not caused by lithospheric fissures, but by convection currents in the mantle, and Jason Morgan (1971) suggested that hotspots are the surface expression of mantle plumes upwelling from the Earth's lowermost mantle. Mantle plumes can be defined as localized upwelling currents of solid rocks that are hotter, and thus less dense, than the surrounding mantle.

Hotspots are traditionally characterized by some or all of the following features, although exceptions do occur: (1) An age-progressive volcanic chain whose linear trend is consistent with the direction of plate motion. (2) The onset of hotspot magmatism is often marked by a Large Igneous

Province (LIP), a term including “continental flood basalts” (CFB) and “oceanic plateaus.” Estimated extruded volumes of CFBs are $1\text{--}2 \times 10^6 \text{ km}^3$, with perhaps similar (but unknown) volumes of intrusive magmatism, whereas oceanic plateaus can be one order of magnitude more voluminous (Coffin and Eldholm 1994). According to the mantle plume initiation model (Richards et al. 1989), the transient and episodic LIP magmatism corresponds to melting of a large plume “head,” whereas the subsequent hotspot activity is associated with the long-lasting and narrow plume “tail.” (3) The topographic swell is a region of anomalously high topography with a lateral width of $\sim 1,000 \text{ km}$ in the direction normal to the volcanic chain (Wessel 1993) and with an elevation of $\sim 1 \text{ km}$, which decreases along the chain. (4) Hotspot basalts are geochemically distinct and more diverse than mid-ocean ridge basalts.

Some hotspots, however, do not show all of the above features. For example, many volcanic chains lack a clear age progression and, according to Ito and van Keken (2007), there are only 13 long-lived ($>50 \text{ Ma}$) and 8 short-lived ($<20 \text{ Ma}$) age-progressive volcanic chains. Some hotspots are not associated with a LIP, whereas others such as the Hawaii and Louisville chains terminate in a subduction zone, so that the complete time record of the volcanic activity is lost. A number of LIPs do not have any volcanic track (e.g., the Shatsky rise and the Hess rise in the Pacific Ocean) and their origin is still a matter of debate. In summary, plume magmatism is often, but not always, explained by the classical thermal plume model with a voluminous spherical head followed by a narrow columnar conduit.

Mantle Plumes, Fig. 1 Seafloor topography from Smith and Sandwell (1997). Numbers indicate some ages (in Ma) along the Hawaiian-Emperor volcanic chain

Mantle Plumes, Fig. 2 Distribution of hotspots (stars) and Phanerozoic LIPs. In red: LIPs (or portions thereof) generated by a transient “plume head.” In blue: LIPs (or portions thereof) generated by a persistent “plume tail.” (Modified from Coffin and Eldholm 1994)

Global Hotspot Distribution and Hotspot Fixity

Over the years, the estimated number of hotspots has varied from 20 (Morgan 1971), to a maximum of 117 in the 1980s, whereas in recent compilations (e.g., Ito and van Keken 2007), the number ranges between 45 and 70 (see Schubert et al. 2001 and references therein). Hotspots younger than 100 Ma are generally active, although their vigor may vary considerably; older hotspots are either waning ($100 < \text{age} < 140$ Ma) or inactive ($\text{age} > 150$ Ma). The best-defined hotspots appear to be relatively stationary over time and are used as a reference frame to determine absolute plate motions. Most hotspots are situated in the oceans, one exception being Yellowstone (USA), whose volcanic activity can be traced back to the 16 Ma-old Columbia River flood basalt. The discrepancy in the number of continental vs. oceanic hotspots has three probable reasons: First, the arrival of a mantle plume can weaken the lithosphere and enhance continental breakup (Courtillot et al. 1999). For example, the magmatic activity of the Iceland plume started with the eruption of the North Atlantic Tertiary Igneous Province (62 Ma ago) and was followed by continental rifting and the appearance of an oceanic spreading ridge after a few million years. In this respect, mantle plumes may have been influential in modifying plate boundaries. The second reason concerns the different thickness (100–150 km) between oceanic and continental lithosphere: weak plumes may not melt beneath a thick continental lithosphere, but are likely to do so at lower pressure, beneath a thinner oceanic lithosphere. Third,

the lack of hotspots in continents could be due to the continents accumulating over downwellings, precisely where plumes are very unlikely to ascend.

The main oceanic hotspots and their related LIPs (Fig. 2) in the Atlantic Ocean are Iceland (0–62 Ma, LIP: the North Atlantic Tertiary Igneous Province) and Tristan da Cunha (0–125 Ma, LIP: the Paraná–Etendeka Province), whereas other hotspots like the Azores (0–20 Ma), Canaries (0–68 Ma), and Cape Verdes (0–Miocene) are not clearly associated with a LIP. In the Indian Ocean, the main hotspots are la Réunion (0–65 Ma, LIP: Deccan Traps), Kerguelen (0.1–120 Ma, LIP: the Kerguelen plateau), and Afar (0–30 Ma, LIP: Ethiopian Traps). In the Pacific Ocean, the main hotspots are Hawaii (0–76 Ma, unknown LIP, since the chain ends in a subduction zone), Louisville (1–77 Ma, possibly 120 Ma if the associated LIP is the Ontong–Java Plateau), and Galapagos (0 to possibly 90 Ma if the associated LIP is the Caribbean Plateau). There are also some hotspots (e.g., in French Polynesia) that may have a plume origin, but with an unclear age progression. Finally, the oceanic floors are “littered” by hundreds of thousands of volcanic seamounts that are certainly not created by plumes (e.g., Hieronymus and Bercovici 2000; Clouard and Gerbault 2008).

An interesting aspect of hotspots is that they are relatively stationary with respect to each other. Their respective motions of 1–2 cm/year are much less than the plate velocities, thereby approximating a fixed hotspot frame of reference. However, Tarduno et al. (2009) calculated the age and the paleolatitude of volcanoes belonging to Hawaiian–Emperor chain and

concluded that the Hawaiian hotspot moved southward at 4–5 cm/year during the period 80–47 Ma ago, whereas it remained relatively fixed (<2 cm/year) afterward. This complex behavior is probably due to the dynamical interaction between upwelling plumes and the “mantle wind” induced by large-scale mantle convection (Steinberger et al. 2004).

Evidence for Mantle Plumes

There is now widespread agreement on the existence of mantle plumes, although contrasting views do exist (see Foulger and Natland 2003 and the web site www.mantleplumes.org). Several lines of evidence support the existence of mantle plumes:

- First, the Earth’s Rayleigh number, which governs the vigor of convection, is sufficiently high (10^6 – 10^8) to insure that mantle convection is time dependent and that its thermal boundary layers (TBLs) become repeatedly unstable. ATBL is a zone characterized by a high-temperature gradient, since heat is transported dominantly by conduction. Fluid dynamical considerations indicate that Rayleigh–Taylor instabilities from a hot TBL generate thermal plumes (Loper and Stacey 1983). A prominent TBL in the Earth’s mantle is possibly the D’ zone, which extends 100–200 km above the core–mantle boundary. The existence of another TBL, for example, at 660 km depth, is still a matter of debate, but it seems unlikely, since the endothermic phase transition does not constitute a complete barrier to mantle convection. Mantle plumes are, therefore, expected to rise from the lowermost mantle, forming cylindrical conduits with a radius of 50–150 km. Such values are based on fluid dynamics, whereas conduit radius estimated by seismology (e.g., Montelli et al. 2004; Wolfe et al. 2009) are much broader.
- Second, seismic detection of narrow plume conduits is challenging, but the first exhaustive study by Montelli et al. (2004) found that at least six plumes (Ascension, Azores, Canary, Easter, Samoa, and Tahiti) extend into the lowermost mantle, whereas others are confined to the upper mantle, and in some cases the model resolution was insufficient. Recently, an extensive ocean-bottom seismological survey of Hawaii (Wolfe et al. 2009) has shown that a low seismic velocity anomaly extends into the lower mantle. Hopefully, future progress in seismic tomography will provide us with further evidence for mantle plumes.
- Third, Oceanic Island Basalts (OIBs) are geochemically distinct and more diverse than Mid-Ocean Ridge Basalts (MORBs), as reviewed by Hofmann (1997). Moreover, isotopic signatures of OIBs indicate an involvement of ancient recycled oceanic crust, as first suggested by

Hofmann and White (1982), whereas noble gases indicate that plumes may also carry primordial mantle material, possibly stored in the deep mantle.

- Fourth, Burke and Torsvik (2004) provide another set of evidence supporting the deep origin of mantle plumes. Their plate tectonic reconstruction over the last 200 Ma shows that the paleoposition of 90% of the 25 LIPs considered, were located, at the time of eruption, above lower mantle regions characterized, today, by low S-wave velocities. These broad regions, situated beneath the South-Central Pacific and Africa (see Romanowicz and Gung 2002 and references therein), are likely hotter and possibly compositionally denser than the surrounding mantle and may indeed represent a long-lived source zone of plumes.

Geochemistry of Mantle Plumes

Geochemists became interested in mantle plumes when they discovered that ocean island basalts (OIBs), thought to be derived from plumes, tend to have different chemical (Schilling 1973) and isotopic (Hart et al. 1973) compositions from mid-ocean-ridge basalts (MORBs). These differences are consistent with the plume model if the deep mantle, the inferred source of plumes, is compositionally different from the upper mantle, source of MORBs. These systematic differences were borne out by many subsequent studies of samples from virtually all available ocean islands (Hofmann 2003), as illustrated by Fig. 3 for chemical compositions and Fig. 4 for isotopic compositions. Both the trace elements and the isotopic compositions indicate that the MORB source has been depleted in “mantle-incompatible” trace elements, that is, those that are scavenged from the mantle by melts that ultimately form the crust, leaving behind a “depleted” mantle. In contrast, plume-type basalts tend to be derived from less depleted mantle sources.

The above observations and conjectures led to the two-layer mantle model, in which “normal” melting producing MORBs and subduction-related magmas have extracted most of the incompatible elements from the upper mantle and sequestered them in the continental crust. By contrast, the lower mantle was thought to be largely undepleted or more “primitive.” Thus, plumes, rising from the deep mantle, would sample the lower, relatively primitive reservoir, but they might entrain more depleted mantle rocks on their way up, thus producing a mixing array between primitive and depleted reservoirs (Jacobsen and Wasserburg 1979). However, mass balance considerations for the incompatible element and isotope budget of the continental crust, the depleted upper mantle, and an undepleted lower mantle, demanded a size of the depleted reservoir of at least 50% of the mantle, which is significantly greater than the roughly 30% mass fraction of the upper mantle. This three-reservoir model

Mantle Plumes,

Fig. 3 Concentrations of selected trace and major elements, arranged in the order of ascending compatibility and normalized to primitive-mantle concentrations, for average continental crust, average MORB, average Mauna Loa, Hawaii, and OIB type representing EM-1 (Enriched mantle 1) and HIMU (high- μ , where $\mu = {}^{238}\text{U}/{}^{204}\text{Pb}$). The patterns for MORB and OIB differ by their enrichments, but show similar Nb and Pb anomalies, opposite to those of the continental crust. (From Hofmann 1997)

Mantle Plumes, Fig. 4 Nd and Sr isotopic compositions^(*) of MORBs and OIBs. EM-1 (Enriched mantle 1), EM-2 (Enriched mantle 2), and HIMU (high μ , where $\mu = {}^{238}\text{U}/{}^{204}\text{Pb}$). The squares indicate compositions of primitive mantle (PRIMA) and of mantle components FOZO and C (see Hofmann 1997 and references therein). ^(*)Some basic notions:

${}^{147}\text{Sm}$ decays to ${}^{143}\text{Nd}$. Since Sm is more compatible than Nd, progressive melting enriches the residual rock in Sm, thus MORBs have high ${}^{143}\text{Nd}/{}^{144}\text{Nd}$. ${}^{87}\text{Rb}$ decays to ${}^{87}\text{Sr}$. Since Rb is less compatible than Sr, progressive melting depletes the residual rock in Rb, thus MORBs have low ${}^{87}\text{Sr}/{}^{86}\text{Sr}$.

(often simply called the “layered mantle” model) was reinforced by the observation that many plume-derived basalts had much higher ${}^3\text{He}/{}^4\text{He}$ ratios than MORB (Farley and Neroda 1998), where ${}^3\text{He}$ is a remnant of primordial noble gases from the primitive Earth, whereas ${}^4\text{He}$ is the product of subsequent decay of uranium and thorium.

In spite of its apparent geochemical persuasiveness, the layered mantle model suffered two essentially fatal blows. During the 1980s, evidence began to accumulate that showed isotopically “enriched” (i.e., crustal-like) mantle sources in several ocean islands including Hawaii, Pitcairn, and Tristan da Cunha. This means that the endpoint of the mixing array of

the type shown in Fig. 4 cannot be an undepleted or “primitive” mantle reservoir but must represent a source component that was crust-like in that it was actually enriched in incompatible elements. And although such a mixing array may pass through the isotopic locus of a primitive mantle reservoir, it clearly does not require the involvement of a primitive reservoir. This is because, when a primitive reservoir is differentiated into enriched and depleted components, any remixing of these differentiated components will produce a compositional array passing approximately through the starting point, the locus of primitive compositions. Therefore, Hofmann and White (1982) proposed that the enriched source components

in mantle plumes actually come from subducted oceanic crust rather than a “primitive reservoir.”

The second blow to the conventional layered mantle model came from seismic evidence showing tomographic images of high seismic velocities characterizing subduction slabs that penetrate the base of the upper mantle and can be traced into the lowermost mantle (e.g., van der Hilst et al. 1997). If such deep subduction occurred during major portions of Earth’s history, convective mixing will have destroyed the chemical separation between upper and lower mantle. The first attempt to integrate numerical convection modeling with chemical differentiation at crustal levels and recycling of ocean crust to generate enriched plume sources at the base of the mantle was made by Christensen and Hofmann (1994), and this has been followed up by more elaborate simulations.

More recently, a variety of new models have sprung up. Some invoke irregularly distributed, relatively primitive plume source regions, which have been protected from convective stirring throughout Earth’s history and are thus able to preserve primitive geochemistry. Tolstikhin and Hofmann (2005) and Boyet and Carlson (2005) have proposed a new form of a two-layer mantle, one in which a relatively small, compositionally dense reservoir formed at the base of the mantle, in effect constituting the D’’ layer. This irregular layer, on average about 200 km thick, has otherwise been interpreted as a “slab graveyard.” The new geochemical model stipulates that these subducted slabs are very ancient, perhaps only a few tens of millions of years younger than the accretion of the Earth. This, in turn, requires stabilization by high intrinsic density, either because they are derived from a primordial iron-rich mafic crust, or because they were generated by downward segregation of dense partial melts in the lowermost mantle (Labrosse et al. 2007) in effect also creating an Fe-rich, dense bulk composition. Such a “new two-layer” mantle model can account for the geochemical differences between plumes and mid-ocean ridge basalts, and it resolves at least two awkward problems with the old model: (1) it does not require that plumes have particularly high helium concentrations, which are never actually observed in plume-derived basalts; (2) it explains trace element characteristics of plume-derived basalts, which are in fact inconsistent with primitive sources. The new two-layer model, by its nature, eliminates the need for any undifferentiated, primitive reservoir, but it creates a repository of primordial noble gases in the permanently sequestered D’’-layer at the base of the mantle. From there, these noble gases can easily diffuse into the overlying actual (silicate) source reservoirs of mantle plumes.

It should be emphasized that, by its very nature, geochemical evidence is extremely unlikely to either prove or disprove the existence of mantle plumes or mantle layering, because the mixing and extraction processes that deliver plume-derived or non-plume-derived melts to the surface are not known a priori. Unfortunately, in the past, it has too often

been argued that some ocean island must be derived from a deep-mantle plume because it contains high $^3\text{He}/^4\text{He}$ ratios, or near-chondritic $^{143}\text{Nd}/^{144}\text{Nd}$ ratios. Indeed, the inherent weakness of such arguments, which are clearly nonunique, has helped to discredit plume theory in some quarters. On the other hand, the plume model in combination with geochemical evidence can help to elucidate many fundamental aspects of Earth evolution, including the timescale of early Earth evolution and of crustal recycling, as well as the intensity of convective stirring in the mantle.

Overall, the “enriched” nature (i.e., enriched in highly incompatible elements relative to more compatible elements), which is evidenced by both the observed trace element and isotope abundances of the decay products of long-lived radioactive decay systems such as ^{87}Rb - ^{87}Sr , ^{147}Sm - ^{143}Nd , ^{176}Lu - ^{176}Hf in plume-derived rocks, is most easily explained by the subduction and recycling of enriched crustal rocks, rather than the involvement of any “primitive” mantle material (Hofmann 1997). Subduction of crustal materials, including ordinary ocean crust, enriched ocean crust, ocean islands and seamounts, as well as some sediments and other continental material, is based on geological and geophysical observations. Thus, there is no shortage of suitable source materials in the mantle without the need for alternative enrichment processes, such as “metasomatic” infiltration, which might nevertheless play some role. The recycled enriched materials appear to be more prevalent in mantle plumes than in mid-ocean ridge basalts, because basaltic crust, once subducted, is somewhat denser than ordinary peridotitic mantle. Because of this, it may be segregated and “stored” at the base of the mantle for geologically longer periods of time, and ultimately contribute significant portions of plume source materials (Christensen and Hofmann 1994).

Genesis and Dynamics of Plumes and Superplumes

On timescales of millions of years, solid mantle rocks behave as highly viscous fluids with a viscosity of $\sim 10^{18}$ – 10^{22} Pa s (in comparison, the viscosity of a glacier is $\sim 10^{13}$ Pa s, and of a basaltic lava is ~ 10 – 10^4 Pa s). Thus, mantle dynamics is governed by a set of equations (conservation of mass, momentum, and energy) for a viscous fluid where inertial effects can be neglected. The growth rate of a Rayleigh–Taylor instability from a thermal boundary layer heated from below is controlled by the Rayleigh number: $\text{Ra} = \rho \alpha \Delta T g d^3 / k \eta$ where ΔT is the temperature contrast across a layer of thickness d , density ρ , thermal expansion coefficient α , thermal diffusivity k , and viscosity η . Instabilities are enhanced by the thermal buoyancy and inhibited by viscosity and thermal diffusivity. Using reasonable values for the above physical parameters, growing instabilities of the boundary

Mantle Plumes, Fig. 5 Numerical simulation of a thermal plume

layer form diapirs. Due to the high mantle viscosity, such a diapir will separate from the TBL only when its volume becomes sufficiently large (e.g., Whitehead and Luther 1975). The morphology of a thermal plume is controlled by the viscosity contrast between the hot fluid and the mantle above it: If the viscosity contrast is weak, plumes will have a “spout” shape, with little difference between the radius of the leading diapir (the plume head) and the following conduit (the plume tail), whereas increasing viscosity contrast leads to a larger head and a narrower conduit. This “mushroom” shape (Fig. 5) is favored, because a hot plume is likely to be 100 times less viscous than the surrounding mantle, owing to the strong temperature dependence of viscosity.

Although fluid dynamics laboratory experiments (e.g., Whitehead and Luther 1975; Griffiths and Campbell 1990) and numerical simulations (e.g., Parmentier et al. 1975; Olson et al. 1993) on purely thermal plumes enabled us to gain a quantitative understanding of plume dynamics, in the 1990s it became progressively clear that the lowermost mantle is compositionally heterogeneous. D'' is a region of preferential segregation and accumulation of denser subducted crust (Christensen and Hofmann 1994), and larger scale regions of the lower mantle may be chemically heterogeneous (Kellogg et al. 1999). This offered new and exciting avenues to explore the complex dynamics of thermochemical plumes, which can be defined as hot (positively buoyant) plumes that carry compositionally denser (negatively buoyant) material. Laboratory experiments by Davaille (1999) investigated a variety of regimes and found that instabilities may form dome-like structures with an oscillatory behavior (i.e., they rise and sink in response to a subtle balance between thermal and chemical buoyancies). Her experiments, together with numerical simulations of thermochemical convection (e.g., Tackley 1998) provide a fluid dynamically consistent framework to interpret observations that are otherwise unexplained by purely thermal convection. For example, the commonly referred “superplumes,” situated beneath the South-Central Pacific and Africa are broad (thousands of kilometers large) lower mantle zones of low seismic velocity most likely associated with active upwelling. Although there is a debate on the thermal and/or compositional origin of “superplumes,”

Mantle Plumes, Fig. 6 Numerical simulation of a thermochemical plume. Top: Temperature field. Bottom: Chemically denser material, represented with tracers. Animations are available

several lines of evidence do support their distinct composition (Ishii and Tromp 1999; Masters et al. 2000). Another issue that can be readily explained by thermochemical plumes is the discrepancy between the petrologically constrained excess temperature of plumes (100–250 °C) and the estimated temperature difference across the D'' region (~1,000 °C). Numerical simulations (Farnetani 1997) show that the deepest, hottest part of the thermal boundary layer does not upwell in mantle plumes if the compositional density contrast exceeds 2%. A denser zone in the boundary layer also tends to “anchor” the base of plume conduit, so that the flow pattern remains stable over timescales longer than the plume rise time (Jellinek and Manga 2002). Finally, thermochemical plumes present a variety of shapes and surface manifestations (Farnetani and Samuel 2005; Kumagai et al. 2007) that expand the classical plume head-tail model predictions (Fig. 6).

Plume Melting and Plume Strength

At spreading ridges, mantle rocks rise to shallow depths in response to plate spreading, and melt by adiabatic decompression (McKenzie and Bickle 1988). This is not the case for most plumes impinging at the base of a preexisting and unrifted continental or oceanic lithosphere. In order to melt at relatively high pressure (4–5 GPa), plumes must be either hotter than normal mantle, or compositionally more “fertile”

than peridotitic mantle (Condie 2001, Chap. 4). Plumes are probably both: their excess temperature is estimated between 100 and 250 °C (Putirka 2005), and they can carry 20%, or more, of recycled crust in the form of eclogite (Sobolev et al. 2007). Eclogite is more fertile than peridotite because it has a lower solidus and a greater melt productivity. According to Sobolev et al. (2005), reaction between eclogite-derived liquids and solid peridotite forms a pyroxenite, whose subsequent melting may explain some compositional characteristics of Hawaiian (and many other plume-derived) lavas. Another efficient way of lowering the solidus temperature is to have fluids (H_2O , CO_2) in the upwelling plume rocks; however, the evidence for “fluid-rich” hotspot lavas is scant. Although it is well known that melting is the most efficient way to create chemical differentiation in the mantle and that it is the unavoidable process to generate surface lavas from mantle rocks, many aspects of partial melting remain elusive (e.g., the pressure–temperature conditions during melting; the source heterogeneous composition; the mechanism of melting, of transport and of storage of the magma). This limits our quantitative understanding of the link between petrological and geochemical observations of surface lavas and the underlying mantle plume composition and dynamics.

The strength of a mantle plume can be calculated on the production rate of volcanic rocks. The method utilizes the volcano’s volume and growth time, and the estimated melt fraction. For example, Mauna Loa has a volume of $\sim 70,000 \text{ km}^3$ and it grew in $\sim 1 \text{ Ma}$, suggesting that the Hawaiian plume melt production rate M is about $0.1\text{--}0.2 \text{ km}^3/\text{year}$. Since only a fraction of the upwelling plume melts, the total plume volume flux $Q_v \gg M$. Another method, based on the rate of swell formation (Sleep 1990), enables one to calculate the plume buoyancy flux $B = Q_v \Delta\rho$ where $\Delta\rho = \rho \alpha (T_{\text{PLUME}} - T_{\text{MANTLE}})$. For Hawaii, the most vigorous hotspot, $B \sim 8,000 \text{ kg/s}$, for Iceland $B \sim 1,400 \text{ kg/s}$, for Galapagos $B \sim 1,000 \text{ kg/s}$. Finally, the plume heat flow is $Q_h = \rho_{\text{MANTLE}} C_p Q_v (T_{\text{PLUME}} - T_{\text{MANTLE}})$, where the specific heat at constant pressure is $C_p \sim 1,200 \text{ J/kg K}$. For Hawaii, the heat flow is $Q_h \sim 360 \times 10^9 \text{ W}$, and it represents $\sim 16\%$ of the global hotspot heat flow of $2.3 \times 10^{12} \text{ W}$, which, in turn is a small fraction of the Earth’s total heat flow of $44 \times 10^{12} \text{ W}$ (for further reading, see Schubert et al. 2001, Chap. 11).

Continental Flood Basalts and Continental Breakup

The eruption of a large igneous province (LIP) represents a major geologic event head. Over the Earth’s history, episodic LIP magmatism contributed to continental growth through the emplacement of CFB and through the accretion/obduction of fragments of oceanic plateaus onto continental crust (Ben-Avraham et al. 1981). Accretion may be due to the

difficulty of subducting the 20–40 km thick crust of an oceanic plateau. Three notable examples of accreted LIP fragments are found in the Solomon Island arc (from the Ontong-Java plateau), in Central America (from the Caribbean plateau), and the Wrangellia terrane outcropping in British Columbia and in SE Alaska (Fig. 7). This allochthonous terrane, locally attaining a thickness of 6 km, is likely to be a fragment of a 230 Ma-old oceanic plateau (Ben-Avraham et al. 1981; Richards et al. 1991; Greene et al. 2008).

Distinctive characteristics of LIP magmatism are the short duration (1–2 Ma) and the huge volumes ($1\text{--}10 \times 10^6 \text{ km}^3$) of eruption. Because of the high eruption rates ($> 1\text{--}2 \text{ km}^3/\text{year}$; for comparison Kilauea grows at $0.1 \text{ km}^3/\text{year}$) and the enormous surface extent ($1\text{--}2 \times 10^6 \text{ km}^2$; for comparison France’s surface is $\sim 0.5 \times 10^6 \text{ km}^2$), flood basalt eruptions are extraordinary volcanic events. CFBs consist of sub-horizontal flows of mafic (Fe- and Mg-rich) rocks, mainly tholeiitic basalts. Individual flows can extend for hundreds of kilometers, be tens to hundreds of meters thick, and have volumes of more than 10^3 km^3 . CFBs are more accessible than submerged oceanic plateaus; however they can be extensively eroded, fragmented, and dispersed on different continents by plate tectonic processes. Clearly, uncertainties regarding the original volume and surface extent increase with their age, for example, for pre-Cambrian CFB only the giant swarm of mafic dikes, feeding surface volcanism, may be left (Ernst and Buchan 2001).

The Phanerozoic CFBs are, in chronological order: The 258 Ma-old Emeishan Traps (SW China), which presently cover only $0.3 \times 10^6 \text{ km}^2$, probably a tenth of the estimated original surface; the 250 Ma-old Siberian Traps, which might have had a surface extent of $3\text{--}4 \times 10^6 \text{ km}^2$ and extrusive volumes of 10^6 km^3 ; and the 200 Ma-old lavas and dike swarms of the Central Atlantic Magmatic Province outcrop in once-contiguous parts of North America (e.g., the Palisades sill, NY), West Africa, and Brazil. This flood volcanism, with an estimated total volume of 3×10^6 to $5 \times 10^6 \text{ km}^3$, preceded the opening of the central Atlantic Ocean. The 184–182 Ma-old Karoo (Southern Africa)–Ferrar (Antarctica) traps preceded the breakup of Gondwana by 10–15 Ma. Similarly, the $\sim 135\text{--}130 \text{ Ma}$ -old magmatism of the Paraná (Brazil)–Etendeka (Namibia) province led to the opening of the South Atlantic Ocean. The Deccan Traps (India) erupted 66–65 Ma ago over an area of the subsequent rifting split apart the Seychelles from India. The North Atlantic Tertiary Igneous Province covers a surface greater than 10^6 km^2 and has an estimated volume of $6 \times 10^6 \text{ km}^3$. The earliest volcanism occurred as flood basalts in Baffin Island, West- and East-Greenland (62 Ma), and later (56–54 Ma) extended to the continental margins of Greenland, the British Isles, and Norway. These rifted edges of continents constitute the so-called volcanic passive margins of up to 8 km-thick seaward dipping basalt layers. The complete opening of the

Mantle Plumes, Fig. 7 Photograph of 1,000 m of continuous subaerial flood basalt stratigraphy in the Wrangell Mountains, Alaska. The yellow line marks the contact between Nikolai basalts and the overlying Chitstone Limestone. (From Greene et al. 2008. With permission)

North Atlantic and the appearance of truly oceanic crust occurred about 53 Ma ago. Finally, the Ethiopian–Yemen traps, ~30 Ma old, have been associated with the rifting in the Red Sea and the Gulf of Aden (Courtilot et al. 1999).

Issues concerning the timing of rifting have been hotly debated: One side claims that rifting preceded, and enhanced, flood volcanism (e.g., White and McKenzie 1989); the other side argues that rifting is not a prerequisite to flood volcanism, since it occurs only during and after volcanism (e.g., Richards et al. 1989). More geological observations are needed, as well as numerical simulations and/or laboratory experiments investigating how anomalously warm mantle can erode the lithosphere and create (or reactivate) weak zones susceptible to rifting.

LIP Magmatism and Environmental Effects

The remarkable temporal correlation between LIP magmatism and mass extinctions of terrestrial and marine organisms suggests a cause-and-effect connection (Courtilot and Renne 2003). The most notable example is the Siberian Traps at the Permian–Triassic boundary (Renne et al. 1995; Svensen et al. 2009). The emplacement of the

Deccan Traps, spanning the Cretaceous–Tertiary boundary, certainly had an environmental effect (Self et al. 2006); however, the extinction event coincided with a large asteroid impact at Chicxulub, Mexico (Schulte et al. 2010). The peak of volcanism in the North Atlantic Volcanic Province corresponds to the Paleocene–Eocene Thermal Maximum (PETM) event 55 Ma ago. Svensen et al. (2004) propose that voluminous magmatic intrusions in carbon-rich sediments induced massive release of the methane buried in marine sediments, thus suggesting that volcanic and metamorphic processes associated with the opening of the North Atlantic may explain global climate events. Self et al. (2006), Ganino and Arndt (2009), and Svensen et al. (2009) attempt to quantify the release of volatiles (CO_2 , CH_4 , SO_2) during flood volcanism and to estimate the consequences on the environment. In particular, the release of volcanic ashes and sulfuric acid aerosols can lead to darkening and cooling, SO_2 and HCl cause acid rains, whereas greenhouse gases like CO_2 and CH_4 cause global warming. Carbon has two origins: magmatic and sediment-derived. Interestingly, Ganino and Arndt (2009) show that the mass of sediment-derived CO_2 can be four to eight times larger than the mass of magmatic CO_2 , if contact metamorphism reactions occur in sedimentary rocks such as dolomite, evaporite, coal, or organic-rich shale. In

other words, the environmental effect of flood basalt magmatism depends, among other factors, on the rock type in contact with magmatic sills and lava flows (Ganino and Arndt 2009; Svensen et al. 2009).

Marine eruptions can also have an environmental effect, because they can cause variations in water chemistry and oceanic circulation. The emplacement of the (Alaska-sized) Ontong-Java plateau 120 Ma ago and of the Caribbean plateau correlate temporally with some of the major Oceanic Anoxic Events (OAEs) which occurred 183, 120, 111, and 93 Ma ago. OAEs are associated with an abrupt rise in temperature, induced by rapid influx of CO₂. The consequent increase of organic productivity causes an increase of oxygen demand in the water column, eventually leading to oxygen depletion in the oceans (for a thorough review see Jenkyns 2010 and references therein). Furthermore, the formation of black shale (marine carbon-rich sediments) may have been favored by massive hydrothermal release of trace metals, poisonous to marine life.

Plume–Lithosphere Interaction

A quantitative understanding of plume–lithosphere interaction enables us to relate geophysical observations (e.g., the spatiotemporal evolution of surface topography, variations in lithospheric thickness, etc.) to the physical parameters and dynamics of the plume. Central issues concerning plume–lithosphere interactions include, but are not limited to the following:

- First, estimating the dynamic topography (Definition of dynamic topography, extracted from Lithgow-Bertelloni and Silver (1998). “Dynamic topography is a deformation of the surface of the Earth, supported by the vertical stresses at the base of the lithosphere, which are generated by flow in the mantle below. This is in contrast to the more familiar mechanism of isostatically supported topography which is in equilibrium at the Earth’s surface and would exist even in a static mantle.”) induced by the arrival of a mantle plume head. Pioneering laboratory experiments by Olson and Nam (1986) found that a thermal diapir upwelling and spreading beneath the lithosphere induces a rapid surface uplift followed by a slower subsidence. According to Farnetani and Richards (1994), uplift should precede flood volcanism by 1–2 Ma, a prediction that is sometimes validated by geological observations (e.g., for the Emeishan Traps), but not always (e.g., for the Siberian Traps). A present-day example of dynamic topography is provided by Lithgow-Bertelloni and Silver (1998), who suggest that the anomalous elevation (~1 km) of South-Central Africa has a dynamic origin, being induced by mantle upwelling from the African “superplume,” a broad lower mantle zone of low seismic velocity anomalies.
- Second, understanding the origin of the topographic hotspot swell and the thermomechanical response of the lithosphere drifting over the plume. Two main mechanisms have been proposed for the Hawaiian swell: “thermal rejuvenation” invokes heating and thinning of the lithosphere above the hotspot, whereas “dynamic support” invokes stresses applied to the base of the lithosphere by the buoyant plume. Seismic studies by Li et al. (2004) around Hawaii found a thinning of the lithosphere from the expected 100 km (beneath the Big Island) to only 50–60 km (beneath Oahu and Kauai, 400 km downstream from the Big Island), thus suggesting a hybrid scenario, whereby “dynamic support” prevails above the plume conduit and “thermal rejuvenation” prevails downstream. Far from the conduit, thermal thinning of the lithosphere may be enhanced by small-scale convective instabilities, which take the form of rolls aligned with the plate motion, as observed in numerical simulations with strongly temperature-dependent viscosity (Moore et al. 1998).
- Third, mechanical and chemical interaction between plume magmas and the lithosphere can explain a number of geophysical and geochemical observations. For example, the occurrence of regularly spaced volcanoes in hotspot chains is probably caused by the interaction of magma transport with lithospheric flexure (Hieronymus and Bercovici 1999, 2000). Under the load of the volcanoes, the lithosphere deforms and the resulting flexural stresses have a key role in determining the locus where magma preferentially extrudes. There are also clear examples of geochemical interaction between the continental lithosphere and plume magmas “en route” to the surface. In particular, CFB lavas erupted at the onset of flood volcanism often have anomalous compositions, reflecting contamination by the lithosphere and crust. It is thus important to quantify the contribution of the continental lithosphere before inferring the plume’s geochemical fingerprint.
- Fourth, plume material may preferentially flow – and partially melt – in preexisting zones of thinned lithosphere (Sleep 1996). In other words, the thickness of the lithosphere and the slope of its base may control the spatial distribution of plume magmatism. According to Ebinger and Sleep (1998), the Cenozoic magmatism in East Africa (including the Afar, the Cameroon volcanic line to the West, and the Comoros Islands to the South) can be explained by a single plume impinging beneath the Ethiopian plateau and its subsequent lateral flow, “channeled” in preexisting rift zones characterized by a relatively shallow base of the lithosphere.

Plume–Ridge Interaction

At least 21 hotspots are situated near a spreading ridge, the clearest examples being Iceland, a ridge-centered hotspot, Galapagos, and the Azores. At Iceland, the Mid-Atlantic Ridge rises ~4 km above normal and remains anomalously shallow for ~1,000 km to the North and the South. Below Iceland, the oceanic crust is 40 km thick, whereas more normal crustal thicknesses of 8–10 km are attained only ~500 km far from the hotspot. Furthermore, compositional anomalies in trace elements and isotope ratios observed along the ridge clearly indicate plume–ridge interaction (Schilling et al. 1985). The Galapagos hotspot is situated ~200 km off-axis from the Galapagos Spreading Center, and, also in this case, geophysical and geochemical anomalies along the ridge suggest plume–ridge interaction. These observations raise several questions concerning: (a) how plume material flows toward the ridge, opposite to the plate motion, (b) how plume material, once “trapped” beneath the ridge, flows parallel to the ridge axis, and (c) how the plume–ridge flow is affected by physical parameters such as the plume volume flux, the plume–ridge distance, and plate velocity. As reviewed by Ito et al. (2003), such questions have been addressed with laboratory experiments (e.g., Kincaid et al. 1995; Feighner and Richards 1995) and theoretical and numerical models (e.g., Ribe et al. 1995; Ribe 1996; Ribe and Delattre 1998) that progressively included more realistic conditions, such as the conductive thickening of the oceanic lithosphere away from the ridge and a migrating spreading ridge. The sloping base of the oceanic lithosphere favors the flow of plume material toward the ridge (Sleep 1996), and the subsequent channeling of plume flow beneath the ridge has been calculated numerically by Albers and Christensen (2001). Such studies concluded that the width over which plume material flows along the ridge increases with higher plume flux and decreases with higher spreading rate and plume–ridge distance (see Ito et al. 2003; Ito and van Keken 2007). Another important parameter is plume viscosity, in particular, Ito et al. (2003) find that the plume flow is reduced by the process of dehydration strengthening, which increases the viscosity of the plume residuum. For a fluid dynamical analysis of plume–ridge interaction see the comprehensive paper by Ribe et al. (2007) and the review paper by Ito et al. (2003).

Summary and Conclusion

This chapter on mantle plumes has taken us from the deep Earth’s mantle where plumes originate, to sublithospheric depths where partial melting occurs, and up to the surface where LIPs have been emplaced in the geologic past, and hotspot lavas are being erupted today. We also explored the

environmental effect of massive LIP volcanism on the oceans and the atmosphere. This range of topics shows that a full understanding of mantle plumes requires a multidisciplinary approach. Important progress will be achieved by linking geophysical, geochemical, and geological observations, to models solving for the fluid dynamics of mantle plumes, melt migration, and physical volcanology, just to mention a few.

Future Directions

In our view, fundamental questions for the future include the following:

1. Quantifying the effect of heterogeneities on plume dynamics and fertility. The term heterogeneity is used here in a broad sense, from small-scale (1–10 km) lenses of recycled eclogite to the large-scale (100–1,000 km) denser superplumes that may generate short-lived instabilities rising from their top. Future studies should model heterogeneous plumes in a fully convecting mantle, with physical properties provided by mineral physics experiments at appropriate temperature and pressure conditions. Lithologic variability affects the fertility and the geochemical characteristics of lavas (Sobolev et al. 2005), but, at present, numerical simulations are unable to model the complex petrological and geochemical evolution of the solid matrix and melts.
2. Quantifying the role of the lithosphere is needed to understand how lithospheric stresses and variations in lithospheric thickness and composition may affect partial melting and the ascent of magma. Hieronymus and Bercovici (2000) provide a theory to explain the distribution of non-hotspot island and seamount chains in the South Pacific and conclude that volcanism can be activated by tensile stresses. The hypothesis that thermoelastic cracking of the oceanic lithosphere (Sandwell and Fialko 2004) can trigger magmatism should be explored quantitatively, to assess the volumes and the composition of such magmas.
3. The cause-and-effect relation between the arrival of a mantle plume and continental breakup is often invoked, but we lack a quantitative understanding of the processes involved. In other words, although there is evidence supporting the role of plumes in the creation and modification of plate boundaries, it is unclear how a large-scale system, with continents and preexisting spreading ridges responds to the arrival of a large mantle plume. Moreover, studies of plume–lithosphere interaction should explore the possibility of dynamic instabilities, such as lithospheric delamination, fingering of low-viscosity fluid, and small-scale convection (see Ito and van Keken 2007 and references therein), and their ability to generate partial melts.

4. Future studies should address in a constructive and quantitative way the current debate (see www.mantleplumes.org) on the “existence of plumes,” or better, on the “coexistence of plumes with other processes” that can produce surface volcanism. Progress will be achieved through improved seismic imaging of plumes and their depth of origin, and through a quantitative understanding of lithospheric processes, as explained above. We also note that much of the ongoing debate questioning the existence of plumes is based on a narrow view of what a plume should look like: the head-tail model is valid in a purely thermal, homogeneous mantle, but a variety of plume shapes are found if the Earth’s lower mantle is compositionally heterogeneous (Farnetani and Samuel 2005; Kumagai et al. 2007). Furthermore, when considering plumes in a convecting mantle, rather than in an unperturbed fluid, it is obvious that conduits cannot be fixed (Steinberger et al. 2004), an observation that does not preclude the existence of deep plumes.
 5. Although we have restricted our treatment to Mesozoic–Cenozoic plumes (<250 Ma), it is likely that plumes had an important role also at earlier times, although geological evidence becomes increasingly scant with geological age (Ernst and Buchan 2001). The early Earth, with its vigorous and highly time-dependent convection, probably had an intense plume magmatism. Hopefully, studies of volcanism on Mars and Venus can complement and improve our knowledge of early terrestrial magmatism (see Condie 2001, Chap. 3). Both Mars and Venus lack plate tectonics, so that old geologic features can be better preserved. On Mars, the Olympus Mons is an enormous shield volcano (volume $2 \times 10^6 \text{ km}^3$), and the Tharsis rise, which covers 20% of the Martian surface, has been volcanically active for the last 2 Ga, suggesting the presence of huge and long-lived plumes in the Martian mantle (Harderer and Christensen 1996).

Mantle Viscosity

W. R. Peltier

Department of Physics, University of Toronto, Toronto, ON, Canada

Definition

The viscosity of the mantle of the Earth is the physical parameter that determines the strength of viscous forces that act when polycrystalline mantle material flows like a liquid on very long timescales. The magnitude of this viscosity is on the order of 10^{21} Pa s, so high compared to water (1 Pa s) that when the mantle flows it does so without inertia.

Introduction

The effective viscosity of Earth's predominantly iron-magnesium silicate mantle is a physical property of fundamental importance. In characterizing this outer shell of the planet by a viscosity at all, one is recognizing that it is capable of flowing as if it were a viscous fluid. This is in spite of the fact that on the timescales characteristic of seismic waves, it is known to be accurately describable as a Hookean elastic solid, albeit one which is endowed with a finite quality factor “Q” due to imperfections of elasticity. The idea that viscoelastic materials may behave as solids on short time scales but as viscous fluids on sufficiently long timescales is well understood in the material science literature. For Earth sciences, the fact that the mantle beneath the almost perfectly elastic surface lithosphere behaves viscously on timescales in excess of a few hundred years, the so-called Maxwell time, is vital to the understanding of plate tectonics and the origins of continental drift as involving the action of thermal convection in the mantle driven by the large contrast in temperature between

Earth's surface and the core-mantle boundary (cmb). This article provides a summary of laboratory and geophysical data that may be brought to bear as a means of measuring mantle viscosity and discusses the compatibility of these measurements with the requirements of the mantle convection process.

Methods of Measurement

One might imagine that laboratory measurements of the creep of mantle mineral assemblages at high pressure and temperature would provide all that is required to obtain the data needed to infer effective viscosity. There are several problems with this idea, however, most of which derive from the difficulty of performing the appropriate experiments under the extreme conditions characteristic of Earth's deep interior. There nevertheless does exist very detailed information on the creep of polycrystalline solids in general which may provide useful insight on the sort of behavior to be expected. Since such polycrystalline aggregates have many characteristics in common insofar as their ability to “flow” is concerned, it is instructive to consider one specific example in order to fix ideas. To this end, Fig. 1 displays a strain-rate vs. differential stress diagram for fine-grained ice (from Goldsby and Kohlstedt 1997), an important model system that has been studied in great detail because of its practical importance in glaciology. In this log-log plot a straight line is indicative of a power law relationship with the slope determining the

Mantle Viscosity, Fig. 1 The rheology of fine grained ($d = 1$ mm) ice at 250 K temperature, calculated using a particular constitutive equation (Goldsby and Kohlstedt 1997)

so-called stress exponent, the power to which the applied differential stress must be raised to predict the observed strain rate. Inspection of the figure will show that, as the differential stress is reduced for a given polycrystalline grain size, the flow law undergoes a series of discrete transitions. At the highest values of differential stress the stress exponent has a value of 4, indicating that the mechanism supporting the “flow” of the polycrystalline aggregate involves the propagation of “dislocations” through the interiors of the individual crystal grains that make up the aggregate. This process is referred to as involving “dislocation climb.” As the differential stress diminishes the stress exponent first drops to a value near 2, indicating that the mechanism supporting flow has come to involve the propagation of dislocations along the boundaries separating individual grains. This regime is referred to as involving “grain boundary sliding.” With even further reduction of the differential stress, the exponent drops to unity implying that the underlying mechanism involves the diffusion of impurities. In this regime, the stress strain relation describing the flow of the solid is now equivalent to that which holds for a simple fluid like water which we refer to as being “Newtonian” as there is a linear relationship between stress and strain rate. Further experimental data also shows that, as the temperature approaches the melting temperature, the strain-rate increases for a fixed value of the differential stress. For the mantle of the Earth, it is therefore understood that the closer the temperature to the melting temperature of the polycrystalline mantle the lower will be the effective viscosity.

Non-Newtonian Rheology from Seismic Anisotropy

It is also generally understood that at shallow depths, from the surface through the near-surface “lithosphere” in which the viscosity is extremely high, the operative rheology is significantly non-Newtonian. The extent to which this behavior persists to greater depth remains undetermined. That the shallow Earth deforms according to a non-Newtonian stress-strain relation follows from the existence of significant seismic anisotropy in this range of depth. The development of such anisotropy requires nonlinearity of the stress-strain relationship in order that individual crystal grains may be aligned by the ambient shear as occurs in the great polar ice sheets on Greenland and Antarctica. Although direct laboratory measurements on the creep of Earth materials at lithospheric depths where the pressures and temperatures are low enough provide useful confirmation of the seismic observations, they are much less illuminating for the Earth’s deep mantle because of the extreme conditions under which measurements must be made to be relevant.

Natural Experiments

In order to obtain useful estimates of the effective viscosity at depths significantly below the lithosphere, which is on the

order of 40–100 km thick, we are obliged to employ the results of “natural experiments” that the Earth itself has performed throughout its history and for which it has also conveniently remembered the results through the fidelity of the geological recording system. The most important experiment is that associated with the Late Quaternary ice-ages, especially the quasi-periodic sequence of glaciation-deglaciation events that began about 900,000 years before present and during which massive accumulations of land ice began to appear and disappear from the continents, especially at high northern latitudes. Insofar as the inference of deep Earth viscosity is concerned, these events may be thought of as comprising an experiment during which extreme normal stresses (force per unit area) were applied to localized regions of Earth’s surface and thereafter removed when deglaciation subsequently occurred. Because the residence time of the land ice on the surface of the continents was sufficiently long compared to the Maxwell time, the response to the applied normal stresses was such as to induce a response of the loaded viscoelastic mantle that involved significant viscous flow. This suggests the possibility that the geological data that represent the Earth’s record of its response to the time-varying ice load might be interpreted to infer the value of the viscosity that governs the viscous component of the response. Also of interest is the question as to whether the viscosity so inferred is compatible with the requirements of the mantle convection explanation of the surface kinematic observations related to the process of plate tectonics.

Mantle Viscosity from Glacial Isostatic Adjustment

Observational Data Sets

Figure 2, from Peltier et al. (2015) and the earlier work of Peltier (1996), shows examples of critical data related to the Glacial Isostatic Adjustment (GIA) process that include maps of the ice-covered regions of the planet under both modern conditions (a), and the conditions that prevailed at the Last Glacial Maximum (LGM), normally thought to have occurred at approximately 21,000 years before present (b). Figure 2c shows an extremely important data set constraining the history of sea level change relative to the surface of the solid Earth at the island of Barbados in the Caribbean Sea from Peltier and Fairbanks (2006). This record covers the interval of time from LGM to the present and has been produced by the Uranium/Thorium dating of corals, the species *Acropora Palmata* being the most important as it normally dwells within 5 m of the surface of the sea while it remains an open system. These data correlate well with the record of ice-equivalent eustatic (globally averaged) sea level history and demonstrate that sea level has risen at Barbados by approximately 130 m since LGM and that the time of Last Glacial Maximum, as determined by the time at which sea level was lowest at

Mantle Viscosity, Fig. 2 (a) Global ice cover and surface topography and bathymetry under modern climate conditions, (b) same as (a) but for Last Glacial Maximum conditions according to the ICE-6G_C (VM5a) model. (c) A fit of the ICE-6G (VM5a) model to the coral based record of

relative sea level history from the island of Barbados. The two major melt water pulses (MWP) are marked. (d) IC-6G_C (VM5a) model fit to the records of Holocene relative sea level history at sites near the centers of rebound of the Laurentide (d1) and Fennoscandian (d2) ice-sheets

Barbados relative to the present level was nearest to 26,000 years before present rather than to 21,000 years before present as has most often been assumed. The Barbados data provide a strong constraint on the total mass of ice that must have been removed from all glaciated regions of the land in order to cause the rise of sea level observed.

As demonstrated in Fig. 3 (also from Peltier et al. 2015), however, which shows in part (a) the locations on Barbados

from which coral samples are available which enable a direct measurement of the long timescale tectonic uplift of the island that is occurring above the subducting Caribbean plate; these data demonstrate that this uplift has been occurring at a rate of 0.34 mm/year over the past several hundred thousand years of Earth history as shown in (b). This implies that the Relative Sea Level (RSL) record from Barbados must be corrected as shown on part (c) of the figure by adding to the depth from

Mantle Viscosity, Fig. 3 (a) Shows the three locations on the island of Barbados at which sub-aerial samples of the *Acropora palmata* species of coral are available that may be employed to determine the rate of tectonic uplift of the island that has been occurring over the past several glacial cycles, (b) rates of uplift inferred at each of these locations, (c) depths of

the radio-carbon dated samples adjusted for the inferred rate of uplift of the island, (d) fit of the prediction of the ICE-6G_C (VM5a) model of the glacial isostatic adjustment process to the inferred sea level history at Barbados

Mantle Viscosity, Fig. 4 Time series for x- and y- components of the location of the north pole of rotation of the planet relative to the coordinate system shown in the inset

which dated samples have been raised, the additional depth by which they have been uplifted due to the influence of local tectonics. This correction amounts to 7 m for samples of LGM age. Part (d) of the figure shows the fit of the ICE-6G_C (VM5a) model of the GIA process of Peltier et al. (2015) to the coral observations after the raw data have been corrected for this influence of local tectonics.

In Fig. 2 (d1,d2) are shown observations of RSL history from sites that were located near the center of the regions in North America and Eurasia, respectively, that were covered by glacial ice at LGM (from Peltier 1998). Whereas the Barbados data record the extent to which sea level was depressed at LGM, these data from the previously ice-covered regions demonstrate that subsequent to the removal of the ice, the land in these regions has been rising out of the sea. This is the process referred to as postglacial rebound of the crust or Glacial Isostatic Adjustment (GIA). The data shown in Fig. 2 (d1, d2) may be quantitatively analyzed to extract information concerning the amplitude and the relaxation time of the characteristically exponential individual sea level curves from such previously ice-covered locations. The relaxation time data inferred on the basis of such data depend most strongly on the mantle viscosity when such records are based upon data taken from the period of time when variations in the initial surface ice load are no longer occurring. Data such as these from hundreds of locations globally constitute one of the primary data sets that may be invoked to constrain the viscosity of Earth's mantle and its depth dependence.

The remaining data related to the GIA process that have come to play an increasingly important role in the inference of

mantle viscosity include those related to the Earth's rotational state. Figure 4 illustrates the first of these additional constraints. It shows the time dependent position of Earth's north pole of rotation in a coordinate system with x- and y-axes centered upon the Conventional International Origin (Vincente and Yumi 1969, 1970). Inspection of the time series in the period between 1900 and 1979, at which time the International Latitude Service which was responsible for maintaining these measurements was discontinued, shows that the measurements are dominated by "beating" at a period very close to 7 years. This is associated with the interference between the 12-month periodic annual wobble of the spin-axis forced by the seasonal variations of the atmosphere and oceans and the 14-month periodic Chandler wobble. The component of these observations that is of interest from the perspective of mantle viscosity measurement, however, consists of the slow secular drift of the pole upon which the oscillatory component is superimposed. These data reveal the secular drift of the pole at a rate near $0.95^\circ/\text{m.y.}$ approximately along the 79°W meridian, i.e., in the direction of present-day Hudson Bay. The rate of this "true polar wander" provides a further constraint upon the viscosity of Earth's mantle.

An additional observational datum that may contribute to the estimation of mantle viscosity consists of the "non-tidal acceleration" of planetary rotation. This datum is illustrated in Fig. 5 where specific times of occurrence of total eclipses of the Sun and Moon are plotted as a function of time spanning the past 2000 years of Earth's history, covering the periods in both Babylon and China during which naked eye astronomers

Mantle Viscosity, Fig. 5 Plot showing variation of time difference between the observed time of a total eclipse of the Sun or the Moon and the predicted time of the event based on the assumption of constant tidal torque over the past 2000 years. The inset (on a scale 25 times expanded) includes the continuous curve derived from the lunar occultations in the period 1620–1995.5 AD. The dashed curve is the best fitting parabola and the solid curve is fitted using cubic splines. (From Stephenson and Morrison 1995)

both recorded and attempted to make predictions of the timing of these “epochal” events (from Stephenson and Morrison 1995). These observations are compared with expectations described by two essentially parabolic curves. The curve that does not go through the data is based on the assumption that only tidal friction has contributed to variations in Earth’s rate of rotation over this period and that this has remained equal to its present-day value, a reasonable assumption. Because the predicted times of occurrence of total eclipses of the Sun and Moon do not agree with expectations based on this assumption, some physical process is missing. The nature of the misfit of this model to the data implies that the action of the missing process is such as to somewhat counteract the influence of tidal friction by decreasing the rate at which Earth’s angular velocity would otherwise decrease. This is called the nontidal acceleration of rotation and it too is a consequence of ice-age loading and unloading of the continents. The curve in Fig. 5 that does go through the data provides a precise measurement of this ice age influence and this may also be employed to constrain the viscosity of Earth’s mantle (e.g., see Peltier 2015).

Results of Inversion of the Totality of the Data to Determine Mantle Viscosity Depth Dependence

In the recent past (e.g., Vacchi et al. 2018), a very careful recompilation of the relative sea level data from the center of rebound in North America, which is located in South East Hudson Bay, has been produced. This has enabled a much

more detailed analysis of the relative merits of competing models of the depth dependence of mantle viscosity. An aspect of the data from this region that merits special attention because of its value, is the constraint provided by the so-called Marine Limit, the maximum height above present sea level ever reached by the sea. Figure 6a shows the complete data set from this region which consists of a very large number of Sea Level Index Points (SLIPs) through which the predictions of any viable model of the GIA process must pass, as well as the Marine Limit data point. Superimposed upon these observations are predictions of the ICE-6G_C (VM5a) model of Peltier et al. (2015) and the ICE-7G_NA (VM7) model of Roy and Peltier (2017). The important Marine Limit data point for SE Hudson Bay is constrained by geomorphological evidence to an elevation of 265 ± 15 m with an age of 8.1 ± 0.3 ka. Part (a) of Fig. 6 also shows the best fitting two parameter exponential model to the same data. A significant additional success of these models has been their ability to explain all of the available Global Positioning System (GPS) measurements of the ongoing rates of vertical motion of the crust across the entire North American continent as well as the Gravity Recovery And Climate Experiment (GRACE) observations of the time dependence of the gravitational field over both North America and Fennoscandia (Peltier et al. 2015). These models also fit the previously described earth rotation observations which are especially important in providing resolving power for viscosity in the deepest part of the lower mantle (Peltier 1998). The

Mantle Viscosity, Fig. 6 (a) Relative sea level observations at the south east Hudson Bay location which is the center of postglacial rebound of the crust that occurred following the complete deglaciation of the North American continent. The data consists not only of the rigorously quality controlled Sea Level Index Points (SLIPS) of Vacchi et al. (2018) but also the Marine Limit data point that records the highest

level on the modern landscape that was once at sea level. Comparisons of the fit to these data are shown for both the ICE-6G_C (VM5a) model of Peltier et al. (2015) and the ICE-7G_NA (VM7) model of Roy and Peltier (2015, 2017). (b) illustrates the VM5a and VM7 viscosity models that represent the current state of the art in spherically symmetric models of this physical property of the planet

depth dependence of viscosity in the VM5a and VM7 models are compared in Fig. 6b. An important property of the VM7 viscosity model is that it is characterized by a continuous increase with depth in the lower mantle, a result that is in accord with expectations based upon the divergence with increasing depth of the mantle adiabat (to which vigorous convection adjusts the mantle geotherm) and melting curve.

Compatibility of the GIA-Based Viscosity Model with that Required by Models of the Mantle Convection Process

An early effort to determine the viscosity of Earth's deep mantle based on GIA data (e.g., Walcott 1970) appealed to the observed magnitude of the free air gravity anomaly over the Hudson Bay region to argue that the magnitude of this anomaly provided strong evidence that the viscosity of the deep Earth was much higher than implied by the analyses described in the previous sections. This anomaly, based on the GEM-T2 model of the Goddard Space Flight Center, is shown in Fig. 7a. It has a maximum amplitude of approximately -30 milligals when the field is restricted to include only spherical harmonic degrees 2 through 8. When the VM2 viscosity model (the precursor to VM5a which is simply a multilayer

fit to VM2) was used in conjunction with a model of ice thickness history in which the maximum thickness was assumed to be coincident with Hudson Bay as Walcott had assumed, the predicted free air gravity anomaly was found to have a peak amplitude of only -3 milligals. This issue concerning the origin of the free air gravity anomaly, was further analyzed in detail by Pari and Peltier (1996). Their work focused on the viability of the alternative hypothesis that the anomaly was supported by the mantle convection process rather than glacial isostasy. Models of mantle convection incorporating the results of seismic tomography (Forte et al. 1994) and based on internal loading theory were developed and applied in analyses of the nonhydrostatic geoid and free air gravity anomalies that would be supported by this mantle dynamic process. In the context of internal loading theory for an Earth model with spherically symmetric viscosity distribution there are only two distinct parameters that need to be specified. The first of these is the depth dependent mapping factor through which the lateral heterogeneity in seismic shear wave velocity is converted into lateral heterogeneity of density. The second is the depth dependence of mantle viscosity. Results were obtained for three different values of the S-wave velocity to density conversion factor in the subcontinental "tectosphere": -0.3 (positive buoyancy, upwelling flow), 0.0 (neutral buoyancy), and $+0.3$ (negative

Mantle Viscosity, Fig. 7 (a) Observed GEM-T2 degree 2 to 8 non-hydrostatic free-air gravity anomaly over the Hudson Bay region of Canada, and (b) the calculated anomaly based on the predictions of the loading theory of the mantle convection process, for the shear wave speed to density conversion factor for the cratonic root of +0.3. Because the pattern of the predicted free air gravity anomaly is extremely well correlated with the satellite observed pattern it is clear that a slight further increase in the local value of the conversion factor would only further improve the fit

buoyancy, downwelling flow). Of the three scenarios, the last model was shown to provide an excellent fit to the free air gravity anomaly (Fig. 7b). A full 24 milligals of the 30 milligal free air anomalies over Hudson Bay could thereby be explained by the mantle convection hypothesis. It needs to be understood that there has been no attempt to tune the model to achieve a best fit locally. Rather the model has been optimized to achieve a best fit to the entire global gravity field. It seems clear on the basis of these results that the free air gravity anomaly over the Hudson Bay region is essentially entirely due to the mantle convection process. Therefore, the original argument of Walcott (1970) that this anomaly must be due to remaining glacial isostatic disequilibrium and to imply that the viscosity of the mantle of the deep Earth below the seismic discontinuity at 660 km depth must be extremely high, is not supported. It seems rather to be explicable as a consequence of thermal convection in a mantle through which the variation of viscosity is rather modest.

The viscosity profile that delivers the high quality fit to the free air anomaly of the North American continent is shown previously in Fig. 5b where it is referred to as VM5a which is very close to the more recent profile referred to as VM7 in that figure. The quality of this model has been further verified by demonstrating it to accurately explain a further observable related to the GIA process, namely the time dependence of the gravitational field measured over the North American continent by the GRACE space geodetic system. As demonstrated in Peltier et al. (2015) the observed field is characterized by the existence of two extrema in gravity field time dependence, one in the south east Hudson Bay region previously discussed above, and another to the west of Hudson Bay coincident with the so-called Keewatin Dome of the Laurentide Ice Sheet. This is further confirmation of the interpretation above that the free air gravity anomaly over Hudson Bay must have an explanation in terms of the mantle convection process. Both

the time dependence of the planets gravitational field and the continent-wide pattern of vertical crustal motion are beautifully explained by the modern theory of the glacial isostatic adjustment process in which the variation with depth of the effective viscosity of the Earth is rather modest.

Summary

This article has reviewed the main sources of information on the viscosity of the deep Earth. These sources consist of data pertaining to the phenomena of postglacial rebound and mantle convection. In spite of modest differences between the models of mantle viscosity depth dependence derived in distinct ways, the overwhelming evidence is that the depth dependence of viscosity derived on the basis of GIA observations is in close accord with that required by the mantle convection hypothesis explanation of surface plate tectonics and continental drift.

Mapping of Magnetic Variations from Space

Nandini Nagarajan

National Geophysical Research Institute, Hyderabad, India

Definition

Magnetic measurements from space, the differences between ground and space measurements, and reduction of satellite-borne measurements are described. Early magnetic measurements in space, the POGO satellite series, with scalar magnetometers provided uniform coverage over the Earth, demonstrated the utility of total intensity measurements that provided the first model of the geomagnetic field, the International Geomagnetic Reference Field (IGRF). First tri-axial

vector measurements were made by MAGSAT Mission that produced IGRF, eliminating ambiguity in the potential field solutions. The Decade of Geopotential Research (1999–2009) wherein concurrent measurements with three satellites with technological improvements were made, expanded the utility and scope of these measurements rapidly. Following this, the present constellation of satellites with gradient measurements further refine studies of geomagnetism. A brief overview of the modelling approaches is presented. In the future, satellite geomagnetism would seek to provide Realtime monitoring, prediction of space weather events, as well as more precise mapping of polar wander, necessary for navigation. Improving measurements, advances in gradient measurements, operability, and cost-effectiveness of missions are some goals.

Measurements from Space

Direct measurements of the magnetic field have been made for a few hundred years, and currently, the field is monitored at approximately 150 geomagnetic observatories on ground. Ground measurements provide reliable temporal signatures of magnetic variation, and reduced to an epoch, produce spatial variations as well. Their spatial distribution is, however, uneven, with large gaps in the oceans, inhospitable terrain, and increasing industrialization. Global surveys required more even coverage and satellite-borne measurements commenced as the technology developed (Olsen et al. 2010; Friis-Christensen et al. 2009). Data obtained from satellites first need to be reduced: by accurately determining the altitude, ellipticity, and position of the satellite, to separate spatial and temporal variation. Reduction of satellite data and comparison with ground measurements presented challenges, since these satellites move at 8 km/s. As a consequence, it is not possible to decide whether an observed magnetic field variation is due to a temporal or spatial change of the field and the signals obtained need to be validated by both time and spatial controls. Another approach is to model the contributions from the Earth's core and crust and well-constrained ionospheric and magnetospheric contributions (Sabaka et al. 2004, 2018).

Efforts to make measurements of the potential field from space, using Low-Earth Orbiting (LEO) satellites started with the launch of OGO (Orbiting Geophysical Observatory) satellite series in the 1960s with an objective to obtain a better understanding of the Earth as a planet and to obtain more data on the Earth-Sun relationship. The LEO satellites attain an initial altitude less than 2000 km and are launched into different orbits based on its purpose. Inclination is an important parameter describing the shape and orientation of a celestial orbit, defined as the angular distance the orbital plane makes with a plane of reference, which is usually the equatorial or ecliptic plane. The LEO satellites having an inclination $>85^\circ$

are called polar LEO satellites. For polar LEO satellites having a perfectly circular orbit, the altitude of the satellite nearly remains constant, whereas for noncircular orbits, its altitude varies depending on the perigee and apogee of the satellite. The polar LEO satellites have an orbital period of 90–100 min, making about 15 orbits in a day, of which half would be in daylight and the other half at night. Except at the poles, the local time of the satellite remains nearly constant in its transit as the satellite moves over nearly constant longitude. With Earth rotating below, the longitude of polar LEO shifts by $\sim 23^\circ$ W after every complete orbit. With this constant shift in longitude every 100 min, on a given day, the polar LEO satellite witnesses nearly the same LT for all 15 day and night passes. The satellite orbit drifts in local time by approximately 1 min each day and hence the satellite visits all LT sectors in nearly 4 months. These attributes of polar LEO satellites make them suitable for the study of geomagnetic processes, since the satellite tracks provide data, covering the whole globe, but each pass remains in constant LT and therefore provides information along longitudes.

POGO Satellite Series

The POGO satellites (Polar Orbiting Geophysical Observatory) were launched in succession in 1965–1971, with near-polar orbits (inclination $>80^\circ$) and apogee heights from 400 to 1500 km. They were equipped with optically pumped rubidium vapor absolute magnetometers and measured only

magnetic field intensity. Intrinsic measurement error of all three satellites is believed to be below 1 nT, but contribution due to position uncertainty results in an effective magnetic error of about 4 nT (Cain and Sweeney 1973; Sabaka et al. 2004; Stockmann et al. 2015).

Though the POGO series of satellites, with scalar magnetometers, in 1960s provided limited coverage, it was enough to prepare the first International Geomagnetic Reference Field (IGRF) model (Cain et al. 1967). The spatial coverage provided by spacecraft was more uniform than any network of observatories, though accuracy was limited. Total magnetic field measurements obtained were used to develop early models of processes affecting the Earth's magnetic field. It was soon realized that such intensity measurements did not provide enough information to recover robust global models of the geomagnetic field. It was established in 1970 as the Backus effect. Backus (1970) proved that for a primarily dipole magnetic field, inversion from intensity data alone is formally nonunique, as two nontrivially different potential fields yield the same intensity everywhere on a spherical surface. It was also demonstrated that the errors of estimation of fields from POGO were linked to this discrepancy.

MAGSAT Mission

MAGSAT, launched after a decade, carried the first vector magnetometers (1979–80) and flew in a near-polar, dawn-

Mapping of Magnetic Variations from Space, Fig. 1 The ground paths of the multiple orbital revolutions during 1 day for a near-polar orbiting satellite. <https://ral.ucar.edu/~djohnson/satellite/coverage.html>

dusk orbit. Scalar and vector data were obtained (Fig. 1). It was equipped with a scalar (cesium) magnetometer, and a tri-axial fluxgate magnetometer which sampled the field at 16 Hz with a resolution of ± 0.5 nT. Attitude was measured using two star-trackers on the spacecraft; transformation of attitude determined by these star trackers to the vector magnetometer located at the tip of the boom was done using a sophisticated optical system. Attitude errors limited the vector data accuracy to about 4 nT rms (Langel et al. 1980; <https://earth.esa.int/web/eoportal/satellite-missions/m/magsat>). Even with a short life of less than a year, MAGSAT provided a data set that resulted in great improvement in the IGRF model of Earth's magnetic field eliminating the Backus effect in magnetic field modelling for the first time. Other achievements using this vector magnetic data set were: detailed lithospheric anomaly maps, delineating more features of the Equatorial electrojet, absolute strength of the magnetospheric ring current, and estimation of F-region ionospheric currents. More significantly, the properties of these vector and scalar data set enabled comprehensive modelling of the different external currents as well as those of internal origin.

Decade of Geopotential Field Research

The Decade of Geopotential Field Research commenced in 1999 with the launch of the Danish satellite Ørsted, nearly 20 years later. CHALLENGING Minisatellite Payload (CHAMP) and the Satélite de Aplicaciones Científicas-C (SAC-C) followed in this international effort to coordinate continuous measurements of the Earth's magnetic field. These satellites had near-polar orbits, lasting 60–90 min, at varying altitudes from 400 to 1500 km. Both Ørsted and CHAMP actively recorded/provided vector data for 10 years (2000–2010), completing 58,277 orbits, far exceeding their designed performance. Extensive tracking by all-sky cameras, tied in with orbital sensing parameters, made it possible to improve time and spatial stamping of data.

Ørsted was fitted with a proton precession Overhauser magnetometer measuring the magnetic field intensity with a sampling rate of 1 Hz and an accuracy < 0.5 nT. A CSC (Compact Spherical Coil) fluxgate vector magnetometer was mounted closely together with a Star Imager. The CSC samples the magnetic field at 100 Hz (burst mode, at polar latitudes) or 25 Hz (normal mode) with a resolution better than 0.1 nT. The measurements are calibrated against the field intensity measured by the scalar magnetometer. After calibration, the agreement between the two magnetometers is better than 0.33 nT rms. Due to attitude errors, the accuracy of the vector components (B_r , B_θ , B_ϕ) is limited to ~ 2 –8 nT (4 nT rms), depending on the component. Initial estimate of mission duration was 14 months, which extended to over 19 years. In

space, the satellite is still healthy and downlinking total intensity data in 2020 (Neubert et al. 2001; <https://directory.eoportal.org/web/eoportal/satellite-missions/o/oersted>)

The Argentinean satellite SAC-C was launched in November 2000, with a copy of the Ørsted boom and payload (but with a US Scalar Helium Magnetometer). SAC-C provided total intensity data, as the vector magnetometer malfunctioned (<https://directory.eoportal.org/web/eoportal/satellite-missions/s/sac-c>).

CHAMP had very similar instrumentation as Ørsted. Differences were: better position and attitude tracking. This enabled reduction of errors and when this system operated over mid and low-latitudes, resolution of ~ 0.2 nT was achieved. Lower orbits of CHAMP produced improved lithospheric field models, new observations of F-region, signatures of night-time currents. The most significant achievement was the unambiguous signatures of induced magnetic fields produced in the oceans (Tyler et al. 2003). CHAMP was also a pilot mission for use of space-borne GPS observations for atmospheric and ionospheric research and applications in weather prediction and space weather monitoring (<https://directory.eoportal.org/web/eoportal/satellite-missions/c-missions/champ>)

Another innovative aspect of Ørsted and CHAMP is that they were both designed to operate over a much more significant period of time. In the case of Ørsted, this is mainly because Ørsted was launched at a higher altitude than Magsat, with the disadvantage of making Ørsted less sensitive to the shortest wavelengths of the field of internal origin. The very different design of CHAMP, reducing weight and cross-section, made it possible to combine the advantages of a long-lasting mission with that of a low altitude orbit.

After calibrating vector magnetometers against the scalar magnetometer, the actual data is used to compute residuals: comparing the two measurements. Despite the improved resolution of magnetometers, errors in attitude and position were factors that resulted in precision of ~ 5 nT for vector measurements. Residuals were minimized in CHAMP measurements, using two all sky cameras and a precision of 2–5 nT was obtained. These satellites improved coverage significantly, overcoming the main limitation of the *Magsat* concept: the sun-synchronous characteristic of its dawn-dusk orbit. Thus, data was obtained in all local times, though each pass was in the same longitude (LT). Availability of two independent systems of magnetometers on board Ørsted and CHAMP provided a check on data quality. The sun-synchronous components of ionospheric origin could be estimated and differentiated. Ørsted and CHAMP provided vector data, concurrently, for several years, and continued to provide scalar data for 10 and 19 years, respectively. SAC-C could only provide scalar data, in 2001–2004. This data was used to validate measurements from the other two satellites and enhanced the accuracy of the combined data set that was

acceptable to model Earth's magnetic field and its processes. After 2004, both Oersted and CHAMP provided only scalar data. A table of the operational details and instrumentation onboard LEO satellites of the past 50 years is provided here (Table 1).

During the Decade of Geopotential Research, the advantages of concurrent measurements by satellites launched in a constellation were demonstrated and this was improved upon with the SWARM Mission that became operational in 2014. The mission comprises of a constellation of three satellites, with two spacecraft to be launched side-by-side at low altitude to measure the East-West gradient of the magnetic field, and a third spacecraft to be launched (with the same launcher) at a slightly higher altitude. The orbital plane of this third spacecraft progressively shifts with respect to the orbital plane of the lower spacecraft pair, to provide data at different local times. Instrumentation that was largely successful in Oersted and CHAMP was deployed.

The constellation of the polar-orbiting trio of satellites was designed to provide north–south gradient information from each spacecraft and unique east–west gradient information from its low-altitude pair of fliers. The orbital planes of the high-altitude flier, known as “Swarm Bravo,” and the low pair, known as “Swarm Alpha” and “Swarm Charlie,” simultaneously sweep out different local times for improved determination of time-varying external fields. (Sabaka et al. 2018: <https://earth.esa.int/web/guest/missions/esa-co-missions/swarm/mission-fact-sheet>)

Modeling of Satellite Measurements

Satellite based measurements of the Earth's magnetic field, both scalar and vector, provided greater spatial coverage than earlier observatory records and ship tracks. It was possible to produce models of the potential field with far better accuracy than before. The generation of large

amounts of data in continuous sequence also posed challenges in estimating time and spatial stamping to preserve acceptable accuracy of measurement. Further, the volume of data required faster and multiple approaches to data reduction and modelling. Modelling methods have kept pace with each improvement in satellite data acquisition from the early satellite missions.

POGO satellite series resulted in some significant advances in estimation of the Earth's magnetic field: the first International Geomagnetic Reference Field (IGRF) (Cain et al. 1967), first global magnetic anomaly map, and observations of external field variations and offered some crucial constraints for reconstructing the core field evolution over the 1965–1971 time period (Regan et al. 1975; Sabaka et al. 2004). *POGO* data have contributed to the definition of lithospheric fields when combined with more recent missions.

Data collected by MAGSAT, in a short duration, contributed to computation of the first higher degree and order models of the field of internal origin, up to order 13, and demonstrated the separation of higher order fields of crustal origin. There were further improvements to lithospheric anomaly maps. In situ observations by MAGSAT also contributed significantly to studies of ionospheric and magnetospheric currents: by observation of meridional currents in the ionosphere, modelling of the Equatorial Electrojet, and estimation of absolute strength of magnetospheric currents. These steps laid the basis for jointly modeling the fields of internal and external origin,

Extensive developments in computational methods, cross-checking by independent teams, and upgrades in data processing provided a greatly improved data set, from the concerted collaborative efforts. The combined data sets of this Decade of Geopotential Research amounted to about 20,000 passes of satellite over any point on the Earth between latitudes $\pm 60^{\circ}$. The volume

of data was huge, including both scalar and vector data. Concurrent data from CHAMP and Oersted provided sufficient quality measurements to model the main magnetic field using quiet night time values, quiet daytime variations due to ionospheric currents, and disturbance currents. First models of induction in oceans were produced from this data set.

Analyzing magnetic data from LEO satellites requires some care, in particular, because they do not orbit in the neutral atmosphere, but in the ionosphere. Some processes that are easily distinguished as being of external origin (ionosphere) and sun-synchronous systems have been characterized from observatory data. Model parameters of these sources were used in preliminary analysis of satellite data. But the same sources are seen as signatures of internal fields by satellites. Separation of these effects, from accurate, vector satellite data with repeated coverage, was achieved with Comprehensive Modeling. Different approaches are: provide a mathematical description of the additional fields, of varying complexity, whereby potential fields and the toroidal fields produced in the upper atmosphere are estimated. This approach, known as the “Comprehensive Modeling” (CM) approach (Sabaka et al. 2004), also makes it possible to take the temporal variations of the various fields into account, despite the fact that the satellites keep on moving.

The further improved approach, using parametrized models of magnetic variations (from ionospheric and magnetospheric sources), together with models of main field and secular variation evolved. This approach – Comprehensive Modeling – was successfully used to extract diurnal variations and effects of well-defined current systems, equatorial and polar electrojets, partial ring currents, etc. Further advances in modelling have been developed and applied to SWARM data, called Comprehensive Inversion (CI) (Sabaka et al. 2018).

Alternately, satellite data at specific times, eliminating atmospheric processes, is extracted to recover the fields of internal origin (main field and secular variation) This method has been successfully applied to data from the SWARM mission, using estimated gradients from two satellites orbiting close together.

Further improvements in modelling made possible with the combination of data obtained at different local times by the SWARM constellation, also allow for an improved determination of the spatiotemporal structure of large-scale external fields, especially of magnetospheric origins. Further, the accurate recovery of time-series of external variations, also makes it possible to separate high-frequency internal signals that are crucial for probing the mantle conductivity structure. Results of such attempts are in publication and further inferences of the internal structure of the Earth will emerge (Fig. 2).

The Future

Continuing evolution of space-borne geophysical measurements have resulted in more accurate and larger volumes of data, over longer durations. Methods of data analysis, comprehensive modelling, and inversion have differentiated between signals from different electromagnetic processes and sources, both external and internal. Mapping of the Earth's magnetic field is now a continuing process with coordinated global initiatives, providing more precise location of the magnetic poles, monitoring space weather, and discerning signatures of both internal and external processes.

Future programs would look to maintain desired accuracy and consistency of data. A significant parameter that has been evaluated by SWARM is measurement of both east-west and north-south gradients. Looking at the analogy between magnetic and gravity fields, the mission concept of GOCE already measures the full gravity gradient tensor of all second space derivatives of the gravity potential (Drinkwater et al. 2003). Aiming at measuring the analogous magnetic gradient tensor (nine component tensor of all three spatial derivatives of all three components of the magnetic field) would thus be a natural next step. In addition to an enhanced high-resolution mapping of the lithospheric magnetic field, such gradient measurements would in fact also allow for an improved in-situ determination of the electric current density in the near-Earth environment. Such an experiment has been conducted with magnetic data taken by ESA's four satellite Cluster constellation mission (Balogh et al. 1997). Constellation flying is, however, very demanding in terms of satellite control and therefore mission energy consumption. An alternative would be with free-flying satellites at varying heights and separations by which it would still be possible to obtain

gradient information at some points in space and time (as in the case of Oersted, SAC-C and CHAMP). A combination of a few very cheap polar orbiting scalar-only satellites augmented by a low-inclination satellite measuring the field vector could be a good and relatively cheap alternative.

Summary

The need for more uniform spatial coverage of coverage magnetic measurements gave rise to the development of satellite-based magnetometry in the 1960s. Several challenges to reducing space-borne measurements in a spatiotemporal frame, with sufficient precision, were overcome, with improving instrumentation and computational methods. The first International Geomagnetic reference field (IGRF) was prepared with total intensity measurements in space combined with ground measurements. Non-uniqueness of this model was later overcome by using both total field and vector magnetic measurements. Improvements in performance of satellites, and magnetometry and tracking systems, have provided a wealth of data by efforts of concerted global initiatives. This resulted in the production of more detailed magnetic anomaly models, distinguishing between external solar-terrestrial effects and internal contribution from the Earth's core, mantle, and crust. The present programs are set to closely monitor changes in the Earth's magnetic field with constellations of satellites, aiming to obtain gradient measurements that would further refine model accuracies.

Microcontinents

Carmen Gaina¹ and Joanne Whittaker²

¹Department of Geosciences, CEED – Centre for Earth Evolution and Dynamics, University of Oslo, Oslo, Norway

²Institute for Marine and Antarctic Studies (IMAS), University of Tasmania, Hobart, TAS, Australia

Definition

Microcontinents are tectonic blocks of continental origin that were detached from continental margins and isolated by oceanic lithosphere. Relocation of plate boundaries, the proximity of mantle plumes, wrench tectonics, and inherited lithospheric heterogeneities play crucial roles in the formation of microcontinents. In the geological record, carving of microcontinents from continental margins, and their transport

and accretion through seafloor spreading and subduction, has constituted an important mechanism for continental lithosphere redistribution. At the same time, microcontinents have likely played a significant role in paleogeography, paleo-ocean circulation, and biogeography.

Introduction

Continents are large masses of rocks with structures and composition that reflects their formation origin (island arcs, volcanism, etc.) and evolution during more than 4 billion years of Earth history. With the onset of plate tectonics 3 billion years ago, ancient continental masses started to be

broken-up or amalgamated with new continental material, which mainly formed in island arc settings. In 1929, Wegener pointed out that the granitic Seychelles Bank in the Indian Ocean (Fig. 1) is a chip of the larger, adjacent continental blocks. He considered the bank to be composed of the more plastic material of the deeper “sial” layers extracted during the rift process (Wegener 1924).

The name “microcontinent” was brought into wide use by Heezen and Tharp (1965) who applied it to various up-standing bathymetric features in the Indian and Atlantic Oceans. They considered any bathymetrically-defined oceanic plateaus and ridges as “microcontinents” regardless of their petrological composition. In the landmark paper “Microcontinents and their significance,” Scrutton (1976) proposed

Microcontinents, Fig. 1 Present-day location of microcontinents (magenta outline) in the Arctic and North Atlantic (upper left) and in all oceans (upper right). Lower panels show 3D bathymetric images of selected microcontinents: (a) Jan Mayen microcontinent (JMMC) in the

NE Atlantic and (b) SW Pacific Ocean (Tasman Sea). The global bathymetry grid is GEBCO 2014. Large igneous provinces-LIPs are shown in light orange. AUS-stands for Australia, DR for Dampier Ridge, EUR for Eurasia, GRN for Greenland, and MdB for Middleton Basin

several criteria for identifying microcontinents: (1) petrological (rocks of continental nature surrounded of oceanic lithosphere); (2) tectonic (the block should have been displaced horizontally relative to the main continent); and (3) morphological (the size of the block has to be significantly smaller than the originating continent).

Microcontinents received increased attention in the last two decades with many studies tackling their structure, formation, and evolution (e.g., Gaina et al. 2009; Whittaker et al. 2016). Today, 29.1% of Earth's lithosphere is continental in nature, but this does not consider additional continental crust that is scattered through the world's oceans as microcontinents (Fig. 1).

Examples of Present-Day Microcontinents

The Jan Mayen Microcontinent in the North Atlantic Ocean

This submerged microcontinent that occupies the central NE Atlantic (Figs. 1 and 2) was already described in the 1970s and 1980s by early scholars who studied the structure and evolution of North Atlantic. Early descriptions focused on its northern part, the Jan Mayen Ridge, a steep-flanked bathymetric horst structure that extends south from Jan Mayen Island. More recent studies based on geophysical data have mapped in more detail the extent of the microcontinent (Gaina et al. 2009), and it is now accepted that it encompasses a number of distinct, structurally controlled tectonic features that were formed by a succession of tectonic and volcanic events. In total, the Jan Mayen microcontinent is 400–450 km long, and varies in width from 100 km in the north to 310 km in the south. However, it has been postulated that the microcontinent may extend further south, into the Iceland plateau and eastern Iceland, as geochemical composition of igneous rocks in SE Iceland point to continental contamination from a source that was preserved under the thick volcanic plateau (Torsvik et al. 2015).

Until very recent, its continental crustal nature was inferred mainly from geophysical data, but now Polteau et al. (2019) describes rock samples recovered from the southern Jan Mayen microcontinent escarpment with ages from Permian/Triassic to Eocene. These rocks also include igneous samples related to the volcanism that accompanied the Early Eocene breakup from the western Eurasian margin. The subsequent isolation of the microcontinent from the western Greenland margin was gradual, with numerous plate boundary relocations to the south of Jan Mayen that led to the formation of its southern highly extended continental crust (Fig. 2). The block was affected by volcanism several times, and its eastern margin was deformed while the microcontinent was rotated to accommodate fan-shaped seafloor spreading in the adjacent Norway Basin.

The Batavia and Gulden Draak Microcontinents in the Eastern Indian Ocean

These microcontinents were discovered in 2011 in the historically sparsely sampled eastern Indian Ocean at the western boundary of the Perth Abyssal Plain (Fig. 1b; Gardner et al. 2015). The Batavia and Gulden Draak microcontinents are 100–200 km in width and length and rise steeply from the abyssal seafloor (~5000 mbsl) to 1500–2000 mbsl. Based on relatively sparse sampling, these two microcontinents are predominantly continental material, with only limited evidence for volcanism. They are composed of granulite facies basement, including pelitic paragneiss and mafic orthogneiss, with inferred Cambrian granite intrusions (Gardner et al. 2015). These continental basement rocks reveal that the microcontinents shared a tectonic history with India, Australia, and Antarctica before the disintegration of East Gondwana. The Batavia and Gulden Draak microcontinents are valuable as the only surviving remnants of the now-destroyed, or highly deformed, Greater India margin.

The microcontinents, as part of Greater India, initially separated from Australia/Antarctica during the Early Cretaceous (~137–136 Ma), followed by formation of ~1600 km of seafloor in the Perth Abyssal Plain over ~36 million years. Isolation of the microcontinents was relatively rapid, occurring through a large-scale relocation of the Perth Abyssal Plain spreading ridge, calving the microcontinents from Greater India 101–104 Myr ago (Whittaker et al. 2016). The calving was primarily driven by a regional/global plate tectonic reorganization event that initiated 105 Myr ago. The reorganization caused a significant change in the relative motion between India and Australia, which initiated transpression along a ~1500 km transform section of the plate boundary, and ultimately triggered the relocation of the plate boundary. The ridge jumped into a region of the Greater India passive margin that had been strongly modified and weakened by ~136–95 Ma volcanism from the Kerguelen mantle plume (Whittaker et al. 2016). This volcanism is widespread across the once conjugate Indian, Australian, Antarctic, and the intervening Indian oceanic lithosphere, including 116.6 Ma volcanism at the northern tip of the Gulden Draak microcontinent.

Formation Mechanisms of Microcontinents

Tectonic forces, inherited lithospheric heterogeneities, and the proximity of mantle plumes may play crucial roles in the formation of microcontinents. A large part of the identified in-situ microcontinents were affected by magmatic activity during continental break-up and sometimes post break-up. Proposed microcontinent formation mechanisms include:

1. The isolation of a small continental piece from a relatively young (less than 25 Myrs old) continental margin requires the proximity to a mantle plume which will

Microcontinents, Fig. 2 Microcontinents (magenta outline or fill) in central NE Atlantic (a) and (b) Perth Abyssal Plain (E Indian Ocean). Present-day maps show free air gravity anomaly in the background. Several submerged plateaus west of Australia (AUS) may be still attached to the main continent by extended continental crust, like the Naturaliste Plateau (NP) and the Wallaby Plateau (WP), whereas the Broken Ridge (BR) is part of a Cretaceous Large Igneous Province. Panels on the right show tectonic reconstructions indicating plate boundary relocations and microcontinent formation. Thin gray and brown lines

are isochrons based on magnetic anomalies showing the extent of oceanic lithosphere. Blue lines are active mid-ocean ridges. Thick grey lines are extinct spreading ridges. The locations of Iceland (Is) and Kerguelen hotspots (K) are shown by the pale red circles. Abbreviations: ANT – Antarctica, AR – Aegir Ridge, B – Batavia, G – Gulden Draak, G-IND – Greater India, KR – Kolbeinsey Ridge, NAM – North America and ZP – Zenith Plateau. Other abbreviations and LIPS polygons are the same as in Fig. 1

trigger one or multiple mid-ocean ridge relocations (Müller et al. 2001). This mechanism explains the volcanism and oceanic lithospheric asymmetries associated with most microcontinents.

2. Changing external plate boundary forces triggering tectonic plate relocations leading to calving of continental lithosphere, and therefore, microcontinent formation (e.g., Whittaker et al. 2016; Gaina et al. 2009).

3. Oblique rifting and strike-slip motion (or wrench tectonics) have been recognized as an efficient way to weaken continental margins and facilitate the isolation of microcontinents (Nemcok et al. 2016). Lithospheric underplating and inherited lithospheric heterogeneities facilitate continental break-up that leads to microcontinent formation when plate boundaries relocate.

Several microcontinents are now trapped in the vicinity of complex subduction zones, like in the Scotia Sea, SE Asia, and Mediterranean Sea, but the role of slab pull or slab roll-back in continental margin break-up and possible microcontinent formation awaits future research.

Summary and Conclusions

At present, microcontinents secluded in the world's oceans may represent 3–4% of the entire continental crust. Extensional and strike-slip motions facilitate continental break-up, and subsequent plate boundary relocations, sometimes due to mantle plume proximity, lead to the isolation of small continental slivers within oceanic lithosphere. Magmatic processes may later affect the microcontinents, and sometimes, they are completely hidden within Large Igneous Provinces. When microcontinents travel on subducting plates, they are subjected to subduction or accretion beneath or onto the upper plate, whose structure and dynamics may be affected both at the collision time and later, depending on the size and shape of the microcontinent. In geological time, microcontinents play important roles for ocean circulation, related climatic events, and paleobiodiversity.

Numerical Methods for Flow in Fractured Porous Media

Luca Formaggia¹, Alessio Fumagalli² and Anna Scotti²

¹MOX, Department of Mathematics, Politecnico di Milano, Milan, Italy

²Department of Mathematics, Politecnico di Milano, Milan, Italy

Definition

Porous medium: A material containing voids (pores), whose size is small compared to the size of the sample.

Fracture: a break in a material with a small thickness compared to its global extension.

Fracture network: a network composed of several intersecting fractures.

Introduction

Fractures are ubiquitous in porous media. Here, with the term fracture we denote a void in the porous material that has the following characteristics:

- (i) One of its dimensions, the aperture, is orders of magnitude smaller than the other dimensions and the size of the domain of interest, but still large compared to pore size. We will indicate with extension the size of a fracture in the directions orthogonal to the aperture. The extension of fractures in a network has a distribution that is usually assumed to be governed by a power law, which implies the presence of a large variation of space scales. See Fig. 1.
- (ii) Fractures may be either open or infilled by a material, whose physical characteristics may be strongly different from those of the surrounding material.

- (iii) Fractures usually form networks, called fracture networks, often highly connected.

With the previous definitions one can consider as fractures, depending on the scale of interest, different objects such as: tectonic faults at the scale of sedimentary basins, cracks in glaciers, as well as fractures in concrete or in rocks.

When they are empty or filled with highly permeable materials, fractures may provide a preferential path to fluid flow, but in some cases the deposits inside fractures can become nearly impermeable. We refer to the latter situation as blocking fracture.

The presence of fractures greatly alters the macroscopic properties of the material in a complex way, in particular its mechanical and flow characteristics. We will be here concerned with the second aspect, and specifically on the mathematical modeling and computing techniques that may be adopted in the presence of fractured porous media. For a more general treatment of fractures in porous media the reader may refer to the book “Fractured Porous Media” (Adler et al. 2012).

The irregular spatial distribution of fractures and the presence of multiple scales make it difficult and often impossible to account for fractures by deriving effective upscaled parameters, permeability for instance, by volume averaging or homogenization techniques. Indeed, such procedures assume a strong separation of scales. Therefore, methods have been developed that model fractures explicitly, at least those crucial for the flow. These models are based on the assumption that in the porous medium flow is governed by Darcy’s law, and often a similar model is adopted for the flow taking place in the fractures as well.

We recall the main characteristic of the Darcy’s model, considering, for simplicity, just the case of single-phase flow. In this mathematical framework the two main variables are the pressure p and the macroscopic velocity field u , also called Darcy’s velocity. The two quantities are related by Darcy’s law (Bear 1972; Helmig 1997),

$$\mu \mathbf{K}^{-1} u + \nabla p = \mathbf{0} \quad \text{in } \Omega, \quad (1a)$$

Numerical Methods for Flow in Fractured Porous Media, Fig. 1 Choice of the numerical model for domains at different space scales

where $\Omega \subset \mathbb{R}^d$ represents the domain occupied by the porous material and ∇ indicates the gradient. In the case where gravity effect are relevant, Eq. (1a) may be modified by replacing the pressure term with $p - \rho g z$, where ρ is the fluid density, g the magnitude of the gravity acceleration, and z is the vertical coordinate pointing upwards from the Earth surface. The main hypotheses behind the model are that fluid velocity is small, so we can neglect inertial effects, and the main model parameters are: μ , the fluid viscosity, and $\mathbf{K}$, the permeability tensor of the porous medium, which is a symmetric and positive definite tensor. Permeability may be heterogeneous in space and often with high variations.

The second equation expresses continuity of mass by the following differential equation (Bear 1972; Helmig 1997),

$$c\phi\partial_t p + \nabla \cdot \mathbf{u} = q \quad \text{in } \Omega, \quad (1b)$$

where $\nabla \cdot$ is the divergence operator, q a source/sink term, c accounts for the medium and fluid compressibility, and ϕ is the porosity. Sometimes one is interested in the steady-state

solution or the compressibility can be neglected, in which case $c\phi\partial_t p = 0$.

Equations (1a) and (1b) form a system of partial differential equations which, complemented by appropriate boundary and initial conditions, allows to describe the evolution of (u, p) in the porous medium.

Numerical Models for Fractured Porous Media

Numerical models for fractured porous media may be subdivided into two main categories: continuum fracture models (CFMs) and discrete fracture models (DFMs).

Continuum Fracture Models

CFMs are early models introduced in the 1960s (Warren and Root 1963), later justified mathematically in (Arbogast et al. 1990), and currently implemented in many industrial software. They assume a highly permeable and interconnected fracture network so that it can be modeled as a continuum superimposed to that of the porous medium.

A commonly adopted method is the dual-porosity/dual-permeability scheme. It assumes that at each point of the domain Ω we may use the Darcy's equations for flow in the fractures and in the porous medium, respectively, with a term representing the interchange of mass between them. A basic model of this type may be written as:

$$\begin{aligned} c_m \phi_m \partial_t p_m + \nabla \cdot \mathbf{u}_m + \alpha(p_m - p_f) &= q_m & \text{in } \Omega, \\ c_f \phi_f \partial_t p_f + \nabla \cdot \mathbf{u}_f - \alpha(p_m - p_f) &= q_f \end{aligned} \quad (2a)$$

where suffixes m and f refer to quantities related to the porous medium and fractures, respectively. The term $\alpha(p_m - p_f)$ represents the mass exchange between the two components, with α a rate parameter. The Darcy's velocities $\mathbf{u}_m$ and $\mathbf{u}_f$ are given by

$$\begin{aligned} \mu \mathbf{K}_m^{-1} \mathbf{u}_m + \nabla p_m &= 0 \\ \mu \mathbf{K}_f^{-1} \mathbf{u}_f + \nabla p_f &= 0 \end{aligned} \quad \text{in } \Omega. \quad (2b)$$

A simpler model, called dual-porosity/single-permeability, may be obtained formally by setting $\mathbf{K}_m = \mathbf{0}$. It assumes that the porous medium acts as storage volume for flow occurring only along fractures. A further simplification, appropriate only for highly connected networks of fracture of small extension relative to the domain size, consists in the use of a single equivalent continuum with upscaled properties that account for the combined effect of porous medium and fractures.

Discrete Fracture Models

DFMs represent fractures explicitly, modeled as a network of (typically planar) surfaces Γ , immersed in the porous medium. In the fractures we typically use a Darcy-type model where

some special source terms are added to account for the fluid exchange with the porous medium. The Darcy equations in the latter are also modified, with terms that act as interface conditions.

DFMs are computationally more demanding than CFMs, but also more accurate, particularly when fractures of relative large extension are present. For this reason the choice between CFM and DFM may depend on the spatial scale of interest, as illustrated in Fig. 1.

On each fracture we may identify a unit normal vector n_f , and thus a positive and a negative side of Γ , see Fig. 2. We indicate with $\llbracket f \rrbracket = f^+ - f^-$ the jump of a quantity f across the fracture.

A commonly used model is derived in Martin et al. (2005), in which the fracture permeability is split into a normal, $K_{f,n}$, and tangential, $K_{f,t}$, components to account for the fact that those quantities may be different and scale differently with the fracture aperture ϵ . In the porous medium $\Omega \setminus \Gamma$ we consider Eq. (1), while in the fractures we have, neglecting the compressibility term,

$$\begin{aligned} \mu K_{f,t}^{-1} u_f + \epsilon \nabla_\tau p_f &= 0 \\ \nabla_\tau \cdot u_f - [u_m \cdot n_f] &= q_f \end{aligned} \quad \text{in } \Gamma, \quad (3a)$$

where $\nabla_\tau \cdot$ and ∇_τ are the divergence and gradient operating on the tangent plane of the fractures, respectively. The jump of normal velocity across the fracture acts as a source term in the mass conservation equation and represent the net flux entering (or leaving) the fracture. This model must be complemented by appropriate boundary conditions. In the portion of the boundary of Γ that touches the boundary of Ω , the conditions are determined by the specific problem at hand: either pressure or mass flux is prescribed. In the case of a fracture tip that ends inside Ω , a zero mass flux condition is generally adopted.

A network normally exhibits intersection between fractures. A common approach is to assume that the pressure is continuous at the intersection and the net sum of fluxes is zero. More sophisticated models are available, to account for fractures with different hydraulic properties and flow along fracture intersections.

To close the problem we need also to specify interface conditions to couple Γ to the porous medium. In Martin et al. (2005) a family of models is presented, including the following, often adopted in practice

$$\begin{aligned} \mu \epsilon K_{f,n}^{-1} u_m^+ \cdot n_f + 2(p_f - p_m^+) &= 0 \\ \mu \epsilon K_{f,n}^{-1} u_m^- \cdot n_f + 2(p_m^- - p_f) &= 0 \end{aligned} \quad \text{on } \Gamma. \quad (3b)$$

These conditions can be interpreted as the application of a discrete Darcy law across the fracture, and indeed they link the flux across the fracture to pressure differences.

Remark 1 If the fractures are highly permeable in the normal direction, continuity of pressure across Γ is often assumed, that is, $p_m^+ = p_m^-$. This induces a certain simplification in the model, since it does not account for a net mass flow across the fracture, but only for porous medium-fracture exchanges.

Remark 2 For nearly impermeable porous media, a different simplification of these models, called discrete fracture networks (DFNs), consists in neglecting the effect of the porous material and simulates flow just in the fracture network. They can be used in the presence of highly connected and permeable fractures.

Discretization Schemes for DFM

Numerical schemes for the approximation of the equations presented in the previous section are based on partitioning the domain Ω into a mesh of polyhedral elements $\mathcal{T}_h$. The unknowns are then discretized by assuming a given variation inside each element, for instance constant or linear. The continuous solution is then replaced by the discrete values at the mesh nodes.

In the case of DFM we need to mesh both the porous medium and fracture domains and construct suitable ways to couple the two via (3b). Many discretization techniques available in the literature may be roughly subdivided into three categories, depending on the relation between porous medium and fracture grids, see Fig. 3.

- (i) Conforming methods. The mesh for the porous medium conforms to that adopted for the fracture network. It means that a fracture mesh element coincides (geometrically) with the faces of two porous medium mesh elements, on the positive and negative side of the fracture. Consequently, no porous medium mesh elements are cut by the fracture. This requirement poses strong constraints on the mesh generation process, which indeed can be the most time-consuming part of the simulation, particularly in the presence of complex networks. On the other hand, the implementation of (3b) is rather straightforward.
- (ii) Non-conforming methods. Still no elements in the porous medium grid are cut by the fractures: however, the grid at the two sides of the fracture and the fracture

Numerical Methods for Flow in Fractured Porous Media,

Fig. 2 Positive and negative side of Γ

Numerical Methods for Flow in Fractured Porous Media,
Fig. 3 Porous medium and fracture grids

grid are independent. The implementation of (3b) involves the setup of suitable operators to transfer the discrete solution in the fractures to the porous medium grid and vice versa. The so-called mortar technique, which is based on the set up of additional variables at the interface, is sometimes used to simplify the construction of the transfer operators. The process of grid generation is eased and it is simpler to avoid the generation of highly distorted elements: however, it is still rather demanding in complex situations.

- (iii) Non-matching methods. The mesh for the porous medium and the fracture network are completely independent and the fracture grids can cut the porous medium mesh elements in an arbitrary way. This simplifies mesh generation greatly, since porous medium and fracture grids can be generated independently. It is still necessary to find the intersections, but this is simpler than generating a conforming mesh and can be done with standard geometric search tools. However, implementation of conditions (3b) is more complex.

For every category, many different numerical schemes are at disposal. For the cases (i) and (ii), it is beneficial to use techniques able to operate on arbitrary polyhedral grids, like finite volumes or mimetic finite differences, to mention the more established one. The research in this field is, however, very active, and we mention also gradient schemes, the hybrid high order (HHO) method, and the virtual elements Method (VEM). A reference containing examples of numerical schemes applied in a DFM context is Fumagalli et al. (2019).

In the case (iii), as already stated, the main difficulty is how to impose the interface conditions. In that respect we have two

classes of procedures. The first is to represent the possible jumps in the solution across the elements cut by a fracture explicitly. This is what is done in eXtended Finite Elements (XFEM), where the finite element basis functions are locally enriched to allow discontinuous solutions that can satisfy the coupling conditions (3b). Contrarily, if one accepts a less accurate representation of the solution, some manipulations of the interface conditions are possible to transform them into source terms acting both on the fracture elements and on the elements in the porous medium that are cut by the fracture. The resulting source terms have some similarity with those present in CFM techniques. The embedded discrete fracture model (EDFM), usually coupled with a simple finite volumes approximation, falls into this second category of methods. A reference on EDFM techniques is in Lee et al. (2000).

The performances of many classes of methods are presented and discussed in Flemisch et al. (2018) for bi-dimensional problems and Berre et al. (2020) for three-dimensional problems.

An Example of Computational Workflow

Numerical simulation of flow in fractured porous media is challenging due to the intrinsic geometrical complexity of the fractures, as well as the measurement of real fractures and their properties buried deep in the underground. These data are difficult to obtain and usually affected by large uncertainty which compromises the reliability of the numerical solutions.

Several approaches can be considered to detect fractures in the underground, from seismic inversion to outcrop interpretation, the former effective to detect big fractures few kilometers below the surface while the latter normally used as an analogue of the underground. Once the fractures are collected and digitalized by means of one of these methods, a suitable mathematical model can be adopted to perform the simulations.

We focus our attention on the case of outcrop interpretation. From highly detailed photographs of the interested region, all the fractures are collected and interpreted up to a minimum sampling scale determined by the quality of the data or by computational constraints. Smaller fractures can be accounted for by a suitable change of the porous medium properties and seen as upscaled or homogenized. What quantity defines a fracture “small” and thus not explicitly represented is still an open question, many authors consider the fracture extension a good proxy for its importance. After this operation, the digitalized version of the outcrop is thus available, see Fig. 4 on the top as an example where natural and human factors limit its exposure. The outcrop is a portion of Sotra Island, near Bergen in Norway.

Another challenging aspect is the collection of the physical data, again affected by uncertainty, that are needed to run the

simulation. If some data are not available, it is possible to fill the gap considering models from the literature to, for example, relate the permeability with the aperture and the latter with the fracture extension. The model can, at this point, be discretized numerically by means of one of the methods mentioned in the previous sections.

Figure 4 reports numerical results of a simulation, in particular the pressure and concentration of a tracer (for instance a contaminant) in the interpreted outcrop. Two extreme cases are considered, if the fractures are more or less permeable than the surrounding porous medium. Data are homogeneous and a left to right pressure gradient is imposed. The solutions are obtained with the library PorePy, see <https://github.com/pmgbergen/porepy>.

Conclusion

Modeling flow in porous media in presence of fractures and fracture networks is a challenging task. Several approaches are available in literature, and a few of them implemented in specialized software. The choice depends on the scales at which the phenomenon has to be considered, on the connectivity of the fracture network and on the level of accuracy desired. Simpler continuum fracture models are suitable for highly connected and dense networks of fracture, while in presence of fracture with a larger extension and more sparse, discrete fracture models provide more accurate results. Clearly, it is also possible to use a combination of the two approaches. In this entry we gave a rapid review of the different strategies and, for the sake of simplicity, we focused the attention on single-phase flow. The general conclusions can however be extended to the more complex situation of multiphase flows.

Numerical Methods, Boundary Element

Michele Cooke

Geosciences Department, University of Massachusetts at Amherst, Amherst, MA, USA

Definition

The boundary element method is a numerical technique for investigating deformation within the Earth. The method is particularly adept at investigations of discontinuities in the crust, such as cracks, faults, and dikes. The numerical method is able to analyze complex problems by discretizing the surfaces of the discontinuities into small elements and solving the problem piecewise.

Introduction

The boundary element method (BEM) is one of several numerical methods used to investigate deformation within the Earth. The principal difference between boundary element

method and most other numerical methods of continuum mechanics, such as the finite element method (FEM), is that only the boundaries of the deforming body need to be meshed (Fig. 1). While other methods require meshing the entire volume of the deforming body into two-dimensional (2D) or three-dimensional (3D) elements, the BEM only requires discretization of the boundaries (e.g., fractures, bedding planes, or external boundaries) into one-dimensional (1D) or 2D elements. Minimizing discretization decreases model building and run time as well as errors due to discretization (Crouch and Starfield 1990). The greatest advantages of BEM modeling in geophysics are that (1) very complicated surface geometries, such as undulating fault surfaces, can be incorporated and (2) the method can readily accommodate fracture propagation by addition of new elements (Fig. 1). The disadvantages of BEM are (1) that the stiffness matrix relating stresses to strains on the elements is non-sparse so that inverting the matrix to find stresses can be very CPU intensive and (2) heterogeneous material properties are more complex to incorporate in BEM than methods that utilize volume discretization, such as FEM (Becker 1992).

How Does BEM Work?

BEM models are based on the solution to Kelvin's problem for the deformation due to a point load within a body. The solution provides the stresses and displacements everywhere due to the point load. We can calculate the effects of distributed loads by integrating the point force. When the loads are applied over discrete elements, the relationships between the displacements at one element due to loads at another are used to build an influence coefficient matrix. When either the displacements or tractions are prescribed to all elements that comprise the BEM model, the method will solve for the unknown element tractions or displacements via the influence coefficient matrix. Once all the displacements and tractions along the boundary elements are known, the stresses and strains at any point within the body can be calculated using the solution of Kelvin's problem. So unlike FEM, where solutions are calculated at each node within the element mesh, within BEM, problems displacements and stresses can be calculated at any point within the body, once all the tractions and displacements along the elements are known.

Numerical Methods, Boundary Element, Fig. 1

Contrasting discretization approaches of the boundary element method and finite element method. BEM only discretizes the boundaries and/or internal surfaces (*blue line*) rather than the entire volume. Fracture propagation is facilitated by addition of elements (*red line*)

Numerical Methods, Boundary Element, Fig. 2 Formulation of the displacement discontinuity along each element within a boundary element method model. The normal and shear displacement discontinuity (D_x and D_y , respectively) are the difference between the displacements along the top and bottom of the element

Two variations of BEMs are commonly used, the *fictitious stress* and *displacement discontinuity* methods. The fictitious stress method is based on Kelvin's problem and applies uniform tractions along each boundary element. In contrast, the displacement discontinuity method applies displacements along each element such that the difference in displacement from one side of the element to the other is constant along the boundary element (Fig. 2). While fictitious stress method works well for homogeneous bodies under external loads, the displacement discontinuity method is better suited for problems of solid bodies containing cracks (Crouch and Starfield 1990). For this reason, the displacement discontinuity method is more common for geophysical analyses, which investigate deformation associated with dikes, sills, microcracks, joints, and faults within the Earth.

What Can BEM Do?

Boundary element method codes using the displacement discontinuity formulation have been developed to solve both two-dimensional (e.g., Crouch and Starfield 1990) and three-dimensional problems (Okada 1992; Thomas 1993; Meade 2007). Two-dimensional formulations use a linear dislocation for each element while three-dimensional formulations utilize either rectangular dislocations (Okada 1992) or angular dislocations (Cominou and Dundurs 1975) that can be assembled to form triangular elements of constant displacement discontinuity (Thomas 1993; Meade 2007). The advantage of triangular elements over rectangular elements is that complex nonplanar surfaces can be meshed without creating locations of overlaps and gaps.

Important refinements to the basic displacement discontinuity method for investigation of problems in geophysics include incorporation of frictional slip along crack elements

and prevention of interpenetration of crack walls during compressive loading of cracks. These refinements facilitate investigation of deformation associated with subsurface faults and joints. Algorithms for preventing interpenetration include the penalty method (Crouch and Starfield 1990; Cooke and Pollard 1997) and the complementarity method (Maerten et al. 2010). The penalty method employs normal and shear stiffness to each element to prevent interpenetration. The complementarity method uses an iterative solver to solve the inequality that opening should be equal to or greater than zero along each element (Maerten et al. 2010).

Heterogeneous properties can be incorporated within BEM formulations by way of a contact boundary. Stresses and displacements are prescribed to be uniform across the boundary between otherwise homogeneous portions of the model. With this constraint along the boundary, the solution for each homogeneous section is found separately. This approach has not been widely applied because it is difficult to implement; finite element methods are generally believed to be better suited for heterogeneous properties.

Applications of the Boundary Element Method

In most BEM implementations, gravitational body forces are superposed onto the solution to the applied loading. This precludes direct investigation of problems related to topographic loading. However, Martel and Muller (2000) developed a formulation for analyzing topographic stresses using a long stress-free crack to simulate the topography.

Investigations of fluid flow through fracture networks has benefited from the surface discretization approach of the boundary element method. Models of subsurface flow through fracture networks utilize a boundary element method model that incorporates fluid flow along each element (e.g., Dershowitz and Fidelibus 1999). Such approaches can permit the full coupling of mechanical deformation and fluid flow.

The boundary element method has found widespread use in the subfield of structural geology for solving problems of deformation and propagation of opening mode and sliding mode fractures (e.g., joints and faults). Both forward and inverse modeling techniques have utilized the boundary element method. Forward models apply loading to the crack system to determine the resulting deformation of the system. Such investigations may explore the development of secondary cracks around a fault or the aperture of a hydraulic fracture. In contrast, inverse models start with the observed deformation and invert to find the slip on the fault or opening on the crack that must have produced the observations. For example, deformation observed along the surfaces of the earth via GPS stations velocities or InSAR imagery can be inverted to find the slip distribution on the underlying fault (e.g., Maerten et al. 2005).

Neumann boundary condition

A condition imposed on the fluxes associated to the differential problem at hand, that is, stresses, heat flux, etc. Also called natural boundary condition.

Parallel computer

A computer with more than one processing unit capable of computing operations concurrently.

Parallel computation

A numerical procedure executed on a parallel computer.

Preconditioner

In the context of the solution of a linear system by an iterative method, a preconditioner is an easily invertible matrix spectrally similar to the matrix governing the problem.

Introduction

Domain decomposition (DD) method is a technique for the solution of partial differential equations which can be instrumental to the development of *parallel computations*. It can be used in the framework of discretization methods, for example, finite elements, finite volumes, finite differences, or spectral element methods.

It is based on the reformulation of the given boundary-value problem on a partition of the computational domain Ω into M subdomains Ω_i , with $i = 1, \dots, M$. Typically M is also the number of processors at disposal, even if it is possible to have more subdomains per processor.

The DD method also provides a convenient framework for the solution of heterogeneous or multi-physics problems, that is, those that are governed by differential equations of different kinds in different subregions of the computational domain. In this case, the subdomains conform with the subregions. In this work, however, we will address only homogeneous DD methods, yet some of the concepts presented here may be readily adapted for the nonhomogeneous case.

We will refer to a partial differential equation of the form

$$-\operatorname{div}(\mathbf{T}(\mathbf{u})) = \mathbf{f} \text{ in } \Omega \quad (1)$$

with suitable boundary conditions on $\partial\Omega$.

For instance, in an elastostatic problem, $\mathbf{u}$ is the displacement and $\mathbf{T}(\mathbf{u})$ the stress tensor; in a heat conduction problem, $\mathbf{u}$ is a scalar variable, the temperature, and $\mathbf{T}$ the Laplace operator. With a rather similar formalism we may also account for the Stokes problem. The method is in fact applicable also to time-dependent problems, since in most cases the time advancing scheme required by the numerical simulation leads eventually to a sequence of problems of type (1). For instance, if we consider the evolution equation

Numerical Methods, Domain Decomposition

Alfio Quarteroni^{1,2} and Luca Formaggia¹

Definition

Computational domain	A bounded spatial region where a partial differential equation is solved.
Dirichlet boundary condition	A condition imposed directly on the unknown of the differential problem, also called essential boundary condition.

$$\partial_t \mathbf{u} - \operatorname{div}(\mathbf{T}(\mathbf{u})) = \mathbf{f},$$

a time discretization by the implicit Euler method leads to solve for the unknown $\mathbf{u}^n$ at each time step t^n a differential problem of the type

$$\mathbf{u}^n - \delta t \operatorname{div}(\mathbf{T}(\mathbf{u}^n)) = \delta t \mathbf{f}^n + \mathbf{u}^{n-1}.$$

It is still of the form (1) with $\operatorname{div}(\mathbf{T})$ replaced by $\delta t \operatorname{div}(\mathbf{T}) - \mathbf{I}$, δt being the time step, and $\mathbf{I}$ the identity operator. A similar form is obtained also for the elastodynamic equations, discretized in time, for instance, by a Newmark method (Quarteroni and Valli 1994).

Typically, and for evident practical reasons, the partition into subdomains is made after having triangulated Ω into a finite element mesh τ_h , each subdomain being in fact formed by a set of elements of the original grid (see Fig. 1). The partition is often made automatically, using libraries like METIS (Karypis and Kumar 1998b) or PARMETIS (Karypis and Kumar 1998a), the latter able to exploit a parallel architecture also for this preprocessing stage.

More in particular, there are two ways of subdividing the computational domain into subdomains. The first uses disjoint subdomains, where $\Omega_i \cap \Omega_j = \emptyset$ for $i \neq j$. Here, the interface between subdomains reduces to surfaces (in 3D) and lines (in 2D). The second strategy adopts *overlapping subdomains*, usually built by letting the subdomains of an initial nonoverlapping partition grow of a certain factor δ . In most of the cases δ is dictated by the number of “layers” of grid elements that are added to the original partition. The minimal overlap is of one element, like that shown in Fig. 1. For a more complete review of DD methods one may refer to Smith et al. (1996), Quarteroni and Valli (1999), Wohlmuth (2001),

Toselli and Widlund (2005), and Mathew (2008); several examples with emphasis on parallel computations are reported, for instance, in Bruaset and Tveito (2006).

Algorithms Without Overlap

We indicate with Γ_{ij} the interface between subdomains Ω_i and Ω_j and we set $\Gamma = \cup_{ij} \Gamma_{ij}$. We exploit the fact that problem (1) is equivalent to solving the following M coupled problems for $i = 1, \dots, M$,

$$-\operatorname{div}(\mathbf{T}(\mathbf{u}_i)) = \mathbf{f}_i \text{ in } \Omega_i \quad (2)$$

with the same boundary conditions of the original problem applied to $\partial\Omega_i \cap \partial\Omega$, while on each Γ_{ij} we set the continuity of the local solutions $\mathbf{u}_i$ and of the fluxes, that is,

$$\mathbf{u}_i = \mathbf{u}_j \quad \mathbf{T}(\mathbf{u}_i) \cdot \mathbf{n}_{ij} + \mathbf{T}(\mathbf{u}_j) \cdot \mathbf{n}_{ji} = 0, \quad (3)$$

where $\mathbf{n}_{ij}$ is the normal to Γ_{ij} outward oriented w.r.t. Ω_i . It may be proved that $\mathbf{u}_i = \mathbf{u}|_{\Omega_i}$ (Quarteroni and Valli 1999).

Problems (2) are coupled because of relations (3). A parallel algorithm may be obtained by an iterative procedure where conditions (3) are enforced in such a way to generate at each iteration decoupled problems that can be run on different processes, with only a small amount of communication needed at the beginning of each iteration. For the sake of space we give an example of just one of these procedures, called *Dirichlet-Neumann* for the case of two subdomains Ω_1 and Ω_2 . Starting from a guess for $u_1^{(0)}$ and $u_2^{(0)}$, the algorithm solves for $k = 1, 2, \dots$ the following sequence of independent problems,

Numerical Methods, Domain Decomposition, Fig. 1 Partition of a computational domain starting from a given triangulation. *Left*: A partition into subdomains with an overlap equal to one layer of elements. *Right*: Partition of a domain with disjoint subdomains

$$\begin{cases} -\operatorname{div}\left(\mathbf{T}\left(\mathbf{u}_1^{(k+1)}\right)\right)=\mathbf{f}_1, & \text{in } \Omega_1, \\ \mathbf{u}_1^{(k+1)}=\theta \mathbf{u}_2^{(k)}+(1-\theta) \mathbf{u}_1^{(k)}, & \text{on } \Gamma_{12} \end{cases} \text{ and } \begin{cases} -\operatorname{div}\left(\mathbf{T}\left(\mathbf{u}_2^{(k+1)}\right)\right)=\mathbf{f}_2, & \text{in } \Omega_2 \\ \mathbf{T}\left(\mathbf{u}_2^{(k+1)}\right) \cdot \mathbf{n}_{21}=\mathbf{T}\left(\mathbf{u}_1^{(k)}\right) \cdot \mathbf{n}_{21} & \text{on } \Gamma_{12} \end{cases}.$$

until a measure of the difference $\mathbf{u}_1^{(k+1)} - \mathbf{u}_2^{(k+1)}$ on Γ_{12} is below a given tolerance; θ here is a convenient relaxation factor. The Dirichlet-Neumann technique is not easily extendable to an arbitrary number of subdomains (unless suitable *coloring techniques* are used) and its convergence characteristics strongly depend on the geometry of the subdomains as well as on the possible jump of characteristic coefficients (for instance, the viscosity of different rocks forming a sedimentary basin). Other more favorable techniques like the Neumann-Neumann, Robin-Robin, and FETI methods are described in Quarteroni and Valli (1999), Wohlmuth (2001) and Toselli and Widlund (2005).

The DD method may be also set from an algebraic viewpoint. Indeed when discretized, for instance, by a finite element method, (2) and (3) reduce to a system of linear equations, which may be written in a block form as

$$\begin{pmatrix} A_{II} & A_{I\Gamma} \\ A_{\Gamma I} & A_{\Gamma\Gamma} \end{pmatrix} \begin{pmatrix} \mathbf{u}_I \\ \mathbf{u}_\Gamma \end{pmatrix} = \begin{pmatrix} \mathbf{f}_I \\ \mathbf{f}_\Gamma \end{pmatrix},$$

where A_{II} is a *block diagonal* matrix with M blocks of dimension equal to the number of unknowns internal to each subdomain, the latter being collected in $\mathbf{u}_I$, while $\mathbf{u}_\Gamma$ is the vector of unknowns on the interface Γ . If A_{II} is invertible (and normally this is the case), we may obtain a problem for the $\mathbf{u}_\Gamma$ only (*Schur complement system*), $\Sigma_\Gamma \mathbf{u}_\Gamma = \chi_\Gamma$, where $\Sigma_\Gamma = A_{\Gamma\Gamma} - A_{\Gamma I} A_{II}^{-1} A_{I\Gamma}$ is the so-called *Schur complement matrix* w.r.t. A_{II} . Having solved for $\mathbf{u}_\Gamma$ the computation of $\mathbf{u}_I$ can be done in a perfect parallel fashion by solving the block diagonal problem $A_{II} \mathbf{u}_I = \mathbf{f}_I - A_{I\Gamma} \mathbf{u}_\Gamma$.

A DD scheme with no overlap may be interpreted as *preconditioned iterative scheme* (Quarteroni and Valli 1994; Quarteroni 2009) for the Schur complement system, where the preconditioner can be efficiently applied in a parallel setting. A crucial issue for parallel computing is that of *scalability*. In the DD setting, an algorithm is said to be scalable if its convergence properties do not depend on the number of subdomains M , and in particular does not degrade if we keep the ratio M/N between number of subdomains and the total number N of unknowns of our problem fixed. Indeed in this case (if we neglect communication overheads), we may solve in the same time a problem twice as large by doubling the number of processors.

A scalable parallel preconditioner cannot be built using only local (i.e., at the subdomain level) approximations of the Schur matrix; we need to add also a *coarse operator* that has the role of transferring information among far away subdomains. The typical form of the preconditioner is (we write directly the inverse operator since it is the one actually required by the iterative procedure (Quarteroni et al. 2007))

$$P_\Sigma^{-1} = \sum_{i=1}^M R_i^T \sum_i^* R_i + R_0^T \sum_0^* R_0, \quad (4)$$

where R_i is a *restriction operator* that selects from all the $\mathbf{u}_\Gamma$ those local to the i -th subdomain, and $\sum_i^*$ is a local approximation of the inverse Schur matrix, which typically can be built using just data related to the i -th subdomain (and thus in parallel). Finally, $\sum_0^*$ is the coarse operator, of small dimension (typically of the order of M), whose role is to guarantee the coupling among all subdomains and it is necessary for scalability. The application of the preconditioner (i.e., the computation of $P_\Sigma^{-1} \mathbf{x}$, where $\mathbf{x}$ is any vector of the right length) can be done in parallel a part from the coarse operator, which however, being small in size, is irrelevant in the computational cost balance. Several scalable preconditioners are available, see Toselli and Widlund (2005) and Canuto et al. (2007).

Methods with Overlap

A typical DD scheme with overlapping subdomains is the Schwarz method. In its basic form, it is an iterative algorithm for the solution of (1) that for $k = 1, 2, \dots$ solves a series of local problems on each subdomain Ω_i , where on the non-empty interfaces $\Gamma_{ij} = \partial\Omega_i \cap \Omega_j$, we apply Dirichlet boundary conditions using the latest values available from Ω_j , that is,

$$\begin{cases} -\operatorname{div}\left(\mathbf{T}\left(\mathbf{u}_i^{(k+1)}\right)\right)=\mathbf{f}_i, & \text{in } \Omega_i, \\ \mathbf{u}_i^{(k+1)}=\mathbf{u}_j^{(k)}, & \text{on } \Gamma_{ij}. \end{cases}$$

The iteration continues until the difference between two successive iterations is sufficiently small. The convergence analysis of the Schwarz method may be found in Smith et al. (1996); Quarteroni and Valli (1999); Toselli and Widlund (2005), and Canuto et al. (2007) in the context of spectral element discretizations.

The method is seldom used in this form, however. Yet, it is probably the most adopted method to build parallel preconditioners for an iterative solver of the global problem, giving rise the so-called *Krylov-Schwarz* (for linear problems) and *Newton-Krylov-Schwarz* methods.

A Schwarz parallel preconditioner P_S may be written similarly to (4), that is,

$$P_S^{-1} = \sum_{i=1}^M R_i^T A_i^{-1} R_i + R_0^T A_0^{-1} R_0,$$

where here the restriction operator R_i extracts from a vector of length N the elements corresponding to the unknowns internal to the extended subdomain Ω_i , $A_i = R_i A R_i^T$ is the local matrix extracted from the matrix A of our problem, and finally A_0 is again a global coarse operator of size of the order M needed for scalability, and R_0 being the corresponding restriction matrix.

Again, apart from the coarse operator, the computation of $P_S^{-1} \mathbf{x}$ can be done in parallel since the matrices A_i are local and can be handled by each processor.

Application to Geophysical and Geological Problems

DD methods have been applied successfully in the context of geophysical problems, like acoustic and elastodynamic wave propagation (Faccioli et al. 1997), or full-waveform tomography (Soubier et al. 2009).

It has been also applied to speed up the simulation of the evolution of sedimentary basins. Here, different types of sediments, such as gravel, sand, rocks, and biological remains that have been transported by the wind, the rivers, and, sometimes, by the sea, accumulate, are buried deeper and deeper, and are transformed eventually into rocks by a complex process of compaction and diagenesis.

On geological scales, the evolution of a sedimentary basin may be tackled by a fluid approach where each rock layer is modeled as a viscous fluid. This is particularly convenient in the presence of salt tectonics (Massimi et al. 2007).

The computational domain Ω is split in several subdomains Ω_i , which usually correspond to the rock layers, as shown in Fig. 2. At each time step, we have to solve in the domain Ω a Stokes problem, possibly with non-Newtonian rheology, to compute the instantaneous velocity field,

$$\begin{cases} -\text{div}(\mathbf{T}(\mathbf{v})) + \nabla p = \mathbf{f}, \\ \text{div}(\mathbf{v}) = \phi, \\ \frac{\partial \rho}{\partial t} + (\mathbf{v} \cdot \nabla) \rho = 0. \end{cases} \quad (5)$$

Here, $\mathbf{v}$ is the velocity, p the pressure, $\mathbf{f}$ the external gravitational field, and ρ the density. The stress tensor $\mathbf{T}$ depends on characteristics of the rocks, such as viscosity and density, which may be discontinuous across layers. The function ϕ may account for compaction processes or may be simply set to zero when the hypothesis of isochoric flow is acceptable. The last equation describes the evolution of the density, which is simply advected by the velocity field. The presence of faults is accounted for by appropriately reducing the rock viscosity in the vicinity of the faults.

The movement of the layers has been tracked using a level set technique. A finite element scheme has been adopted for the discretization of the Stokes problem, while a conservative finite volume scheme has been used for the tracking of the layer interfaces. The parallel implementation has been carried out with the help of the TRILINOS library (Heroux et al.

Numerical Methods, Domain

Decomposition, Fig. 2 The simulated evolution of a salt diapir. In the first graphic, the computational domain showing the subdivision of the layers. The other pictures show snapshots of the evolution of the salt layer with the formation of a diapir

2005), using a Schwarz algorithm with a coarse operator built by aggregation (Sala 2004).

Figure 2 shows the evolution of a salt dome. Salt is less compressible than the surrounding rock, so during the sedimentation process it ends having a smaller density than the overburden. We are then facing a Rayleigh-Taylor instability and any small perturbation will cause the salt to rise, with large movements that cause the so-called salt diapirism.

Definition

Finite-difference method. A method to approximate derivatives between neighboring points in a grid. The method can be applied to solve partial-differential equations, such as the wave equation.

Introduction

The finite-difference (FD) method is among the most commonly used methods for simulating wave propagation in a heterogeneous Earth. In this article, we describe the FD method for modeling wave propagation on Cartesian grids in acoustic, elastic isotropic, elastic anisotropic, as well as viscoacoustic/elastic media. The basic equations for wave propagation can be formulated in various formally equivalent ways. We will restrict our description to systems of first-order partial-differential equations with pressure/stress and particle velocities as wavefield variables. Due to its versatility, attractive stability, and dispersive properties, particularly for modeling wave propagation in elastic media, this formulation has been by far the most popular formulation over the last several decades. A more extensive review of the FD method is given by Moczo et al. (2007).

We start with a brief review of wave propagation theory and introduce some fundamental concepts including the basic structure (staggering) of the FD grid. In the following two sections, we discuss the choice of FD approximation and introduce two basic numerical properties of the FD method: numerical dispersion and stability. The last two sections are devoted to different boundary conditions and source implementations.

Theory of Wave Propagation and Fundamental Concepts

We focus on wave propagation in 3D Cartesian coordinates with coordinate axes (x, y, z) . The special cases of 1D or 2D can easily be generalized from the expressions presented here, for example, in 2D, omitting terms or expressions containing components in the y -direction. The particle velocity wavefield is denoted by $\vec{v} = (v_x, v_y, v_z)$. In acoustic media, the second wavefield variable is the scalar quantity pressure, p , whereas

in elastic media it is the (symmetric) stress tensor, S . We will often be representing stresses and particle velocities using stress and strain vectors defined as (the so-called Voigt notation):

$$\vec{\sigma} = (\sigma_{xx} \ \sigma_{yy} \ \sigma_{zz} \ \sigma_{yz} \ \sigma_{xz} \ \sigma_{xy})^T,$$

and

$$\vec{\epsilon} = (\epsilon_{xx} \ \epsilon_{yy} \ \epsilon_{zz} \ 2\epsilon_{yz} \ 2\epsilon_{xz} \ 2\epsilon_{xy})^T,$$

where the strain vector is related to the particle velocity vector components through:

$$\frac{\partial \vec{\epsilon}}{\partial t} = \left(\frac{\partial v_x}{\partial x} \ \frac{\partial v_y}{\partial y} \ \frac{\partial v_z}{\partial z} \ \frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y} \ \frac{\partial v_x}{\partial z} + \frac{\partial v_z}{\partial x} \ \frac{\partial v_y}{\partial x} + \frac{\partial v_x}{\partial y} \right)^T.$$

The system of equations for wave propagation consists of two (dependent) sets of equations. First, the equation of motion (or Newton's second law):

$$\rho \frac{\partial \vec{v}}{\partial t} = \nabla \cdot \vec{S} + \vec{f}, \quad (1)$$

where ρ is the density of the medium, $\nabla \cdot \vec{S}$ denotes divergence of the stress tensor and $\vec{f}$ is a point-force source (source formulations driving the FD simulations will be described in detail later). In an acoustic medium, only the diagonal elements of the stress tensor are non-zero and equal to the negative pressure $-p$.

The second set of equations for wave propagation is the constitutive stress-strain relation:

$$\frac{\partial \vec{\sigma}}{\partial t} = C \frac{\partial \vec{\epsilon}}{\partial t}, \quad (2)$$

where C is the 6-by-6 stiffness matrix. For an elastic isotropic medium, the stiffness matrix takes the form:

$$C = \begin{pmatrix} \lambda + 2\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda + 2\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda + 2\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu \end{pmatrix}, \quad (3)$$

whereas in a general anisotropic medium, all components of the stiffness matrix may be non-zero. As we shall see, this has profound implications on the choice of grid geometry to discretize the constitutive relation. Finally, although redundant, the acoustic constitutive relation can also be written using the notation of the stiffness matrix and the stress-strain

constitutive relation. As noted above, instead of a stress vector with three independent components, we obtain:

$$\vec{\sigma} = -(p \ p \ p \ 0 \ 0 \ 0)^T. \quad (4)$$

In an acoustic medium, only the (3-by-3) upper left quadrant of the stiffness matrix is non-zero, with all elements equal and identical to the bulk modulus of the acoustic medium κ . Clearly this results in three identical equations – the familiar Hooke's law: $\frac{\partial}{\partial t} p = -\kappa \nabla \cdot \vec{v}$.

The FD method comprises solving Eqs. 1 and 2 by discretizing them in time and space and stepping forward in small incremental time steps. In particular, the exact choice of discretization in space turns out to be of fundamental importance. The so-called staggered grid was introduced for modeling isotropic elastic wave propagation by Virieux (1986) and Levander (1988, 1989). In the following, we will be referring to this as the Virieux grid. The choice of this grid results in schemes with attractive stability and dispersion properties, which other non-staggered grids do not necessarily possess. FD approximations to first-order derivatives naturally result in outputting the derivative of the wavefield at a location in between the discretized wavefield. By shifting the exact location of individual wavefield components by half a grid step in certain directions within each grid cell, it is possible to ensure that spatial derivatives can be computed exactly at the locations where they are needed to advance canonical wavefield quantities in time using Eqs. 1 and 2. The structure of the Virieux staggered grid is illustrated in Fig. 1a. The Virieux grid is also a good choice for modeling wave propagation in acoustic media. The resulting sparsely populated staggered-grid cell is equivalent to Fig. 1a but without the shear stresses populating the grid cell (small blue balls in Fig. 1a). In many situations, it is desirable to have a computational model that may contain both acoustic and elastic regions (e.g., modeling a marine seismic experiment or the seismic response of magma chambers). This is straightforward using a Virieux grid, by simply setting $\lambda = \kappa$ and $\mu = 0$ in Eq. 3 in the acoustic regions. Updating the equations will guarantee that the “acoustic stress vector” in Eq. 4 is satisfied to within-machine precision.

The Virieux grid is the natural choice for modeling wave propagation in elastic media as long as the stiffness matrix, C , in Eq. 2 belongs to a class of anisotropic materials referred to as orthorhombic media and as long as the symmetry axes of the medium are aligned with the Cartesian grid (isotropic media is a special case that belongs in this family of media). For this class of anisotropic materials, all elements that are zero in Eq. 3 remain zero. However, as soon as we introduce more complex anisotropic symmetry classes or rotate the symmetry axes with respect to the grid, the elements that are zero in Eq. 3 will become non-zero. As a consequence, Igel et al. (1995) noted that spatial derivatives are no longer

Numerical Methods, Finite Difference, Fig. 1 Staggered-grid geometries. (a) (left): Virieux staggered grid (1986). Large blue ball: normal stress components; small blue ball: shear stress components; red arrows: particle velocity components in the directions indicated. (b) (Right): Lebedev staggered grid (Lisitsa and Vishnevskiy 2010; Bernth

and Chapman 2010). Large blue ball: all stress components; large red ball: all particle velocity components. The authors acknowledge Chris Chapman and Henrik Bernth (Schlumberger Cambridge Research) for providing the figure

available at all locations where they are needed. Igel et al. (1995) solved this by interpolating strains between their natural locations. However, the scheme is both expensive and results in fairly complex implementations. Saenger (2000) solved the problem in 2D by observing that a rotation of the staggered grid by 45° results in a natural choice for staggering the wavefield quantities so that no interpolation is necessary. The so-called rotated staggered scheme can also be generalized to 3D, although it can no longer be seen as a simple rotation of the Virieux grid. Another staggered grid that avoids the necessity to interpolate wavefield quantities in anisotropic media is the Lebedev grid (Lisitsa and Vishnevskiy 2010), which is illustrated in Fig. 1b. Bernth and Chapman (2010) analyzed and compared the different staggered-grid geometries and concluded that whereas the rotated staggered grid and the Lebedev grid are equivalent in 2D, the Lebedev grid is different and a better choice compared to the rotated staggered grid in 3D. The Lebedev grid is both computationally more efficient and also lends itself to a simpler implementation as it can be regarded as a combination of four independent Virieux grids that decouple in isotropic media.

So far, the discussion in this section has concerned lossless media. In order to account for attenuation, a viscoacoustic or viscoelastic model is introduced by using a different constitutive stress–strain relation compared to Eq. 2. Equation 2 can be thought of as a model of springs connecting particles in a lattice. When compressing the springs, energy is stored for an infinite time or until the compressed springs are released after which the particles return to their original positions. In a viscoelastic medium, dashpots are introduced in parallel or in series with the springs causing energy to dissipate after compression. The stiffness matrix becomes time-dependent and the multiplication with the time derivative of the strains is

replaced by a convolution in time. The new viscoelastic constitutive relation becomes:

$$\frac{\partial}{\partial t} \vec{\sigma} = G(t) * \frac{\partial}{\partial t} \vec{\epsilon}, \quad (5)$$

where $G(t)$ is the new relaxation stiffness matrix, which contains elements that are functions of time. Such a particularly useful function corresponds to a spring/dashpot configuration called a standard linear solid (Robertsson et al. 1994). First, due to the exponential kernel (in time) in the relaxation function of a standard linear solid, the convolution in Eq. 5 can be eliminated at the expense of introducing a new set of differential equations to be solved at each time step and spatial location. No additional complications due to various grid geometries arise after introducing the new differential equations solving for the so-called viscoelastic memory variables as these equations are fairly simple ordinary differential equations in time (as opposed to partial-differential equations with additional spatial derivatives). Second, Robertsson et al. (1994) and Blanch et al. (1995) showed how arrays of standard linear solid elements can advantageously be used to model constant quality factor Q versus frequency and also how to model attenuation of P and S waves in elastic isotropic media separately. However, exactly what attenuation to model for different wave types in an anisotropic medium is unclear and remains a topic for research (there are no pure P and S waves in an anisotropic medium).

Finite-Difference Approximations

The FD method approximates derivatives by combining neighboring function values on a grid, where the particular

combination is commonly derived using the Taylor expansion of the function at the different sample points. The simplest example of a FD approximation is the first derivative of a function p at x_0 using only two samples:

$$\frac{\partial p(x_0)}{\partial x} = \frac{1}{\Delta x} \left(p\left(x_0 + \frac{\Delta x}{2}\right) - p\left(x_0 - \frac{\Delta x}{2}\right) \right) + C_1 \frac{\partial^3 p(x_0)}{\partial x^3} (\Delta x)^2 + O((\Delta x)^4), \quad (6)$$

where Δx is the sampling interval and C_1 is a constant. The lowest-order error term in this expansion is proportional to the square of the sampling interval. Hence, as we decrease Δx , the FD approximation will become increasingly accurate (the increase in accuracy proportional to the square of Δx) and in the limit be equivalent to the first derivative of p . The approximation is therefore considered second-order accurate since the lowest-order error term depends on the square of the sampling interval. Higher-order approximations of the first derivative can be expressed as a weighted sum of additional adjacent sample points:

$$\frac{\partial p(x_0)}{\partial x} = \frac{1}{\Delta x} \sum_{i=1}^M \alpha_i \left(p\left(x_0 + \frac{(2i-1)\Delta x}{2}\right) - p\left(x_0 - \frac{(2i-1)\Delta x}{2}\right) \right) + O((\Delta x)^{2M}). \quad (7)$$

The coefficients α_i describe what is often called the FD stencil and are chosen such that terms containing lower-order error factors are canceled (Table 1).

The accuracy of the FD approximations for the temporal derivatives and the spatial derivatives are often different and schemes are accordingly named with two accuracy orders. An $O(2,8)$ accurate scheme would be second-order accurate in time and eighth-order accurate in space.

From Eq. 6, we note that the derivative estimate of a spatial derivative is computed in between sample points of the wavefield quantity in question. As described in the previous section, this is the reason why the staggered-grid formulation is particularly well suited for FD modeling of the system of first-order differential equations describing wave propagation. The grid staggering is also applied in time, typically utilizing the simple second-order accurate approximation in Eq. 6, resulting in a time-stepping method referred to as a “leap-frog” scheme. The leap-frog scheme is in turn referred

to as an explicit FD scheme since the differential equations only contain one unknown after discretization in space and time, and which, therefore, can be computed directly without solving further systems of equations. For example, if we are in the process of updating particle velocities at a new time step $t_0 + \Delta t$ using Eq. 1, we can compute the particle velocities directly from the known particle velocities at time t_0 and through spatial FD approximations of the known stresses at time $t_0 + \Delta t/2$. We then proceed to update stresses at time $t_0 = 3\Delta t/2$ using Eq. 2 explicitly from the stresses at $t_0 + \Delta t/2$ and particle velocities at $t_0 + \Delta t$. In this fashion, we march through the FD simulation until we reach the desired maximum time of the simulation. Clearly, we need to initiate the simulation with so-called initial conditions for particle velocities at time 0 and stresses at time $\Delta t/2$.

Accuracy and Numerical Dispersion

The most visible error introduced through the FD approximation is called numerical dispersion and appears when either the sampling interval is too large or the approximation is not of sufficiently high order. Numerical dispersion is defined as the effect when different frequencies of the wavefields propagate slower or faster compared to the correct speed of wave propagation in the medium. Figures 2 and 3 show wave propagation simulations with two different order schemes using the same spatial sampling and clearly demonstrate severe effects of numerical dispersion of the lower-order scheme.

The numerical dispersion can be predicted by Fourier transforming the FD expressions in time and space. Using the Fourier-transformed expressions, we obtain a relationship that shows how the propagation velocity in the medium is affected by numerical dispersion. It is a function of several parameters including the spatial grid step and the so-called Courant number (see stability section below). Figure 4 shows several such dispersion curves (phase velocity error as a function of the number of wavelengths per gridpoint) for different choices of time steps (resulting in different Courant numbers, see below). The numerical dispersion is dominated by the slowest wave speed in the medium, where the wavelength is the shortest. The number of sampling/gridpoints per wavelength necessary for a certain level of accuracy is thus determined by the dispersion curve and the slowest wave speed in a medium.

In practice, it is still difficult to define exactly how fine the wavefields must be sampled to avoid numerical dispersion as the severity of the numerical dispersion depends on the accuracy of the approximation and how far the wave has to propagate. However, as general rules of thumb, in order to roughly limit effects of numerical dispersion within a 2.5% error in propagation velocity, an $O(2,4)$ scheme requires at

**Numerical Methods,

6	75/64	-25/384	3/640

Numerical Methods, Finite Difference, Fig. 2 Snapshot in time of a simulation using the acoustic wave equation. The black-and-white wave front indicates the location of a travelling wave. The wave has been reflected in the upper free surface and changed polarity. The left side shows the radiating boundary condition, which in this case is a PML. The blue area has slower propagation velocity than the red area. The solution has been computed using an $O(2,16)$ scheme

Numerical Methods, Finite Difference, Fig. 3 Similar snapshot in time to that shown in Fig. 2. The spatial sampling and medium is the same as in Fig. 2, but in this case the simulation has been performed with an $O(2,2)$ scheme. The trailing ripples of the wave front are typical for numerical dispersion

least eight grid points per minimum wavelength, whereas an $O(2,6)$ scheme requires six grid points per minimum wavelength.

It is obvious from Eq. 8 that a higher-order derivative approximation requires more computations than a lower-order approximation. However, in general higher-order approximations (up to some limit) are preferred as the computational requirements increase linearly with accuracy order, whereas a finer grid increases the computational requirement to the fourth power of the refinement in 3D. The fourth power dependence originates from the fact that the temporal step must be proportional to the spatial step (see [Time Stepping and Stability](#) below). Thus, if the spatial step is reduced by a factor n , then a factor n^3 more gridpoints are required in 3D in addition to another factor n more time steps, therefore resulting in an increase of a factor n^4 in the number of computations required.

Lax–Wendroff Corrections, Optimally Accurate FD Schemes and Time Dispersion Correction

The higher-order FD approximations are usually applied to spatial derivatives. To construct a functional scheme that has a higher order of accuracy in time, it is often necessary to use implicit time stepping, which results in a substantial increase in computational requirements. A solution to increase the formal order of accuracy (in a Taylor sense) without resorting to implicit schemes or saving several time levels is to apply a so-called Lax–Wendroff correction (Dablain 1986). The Lax–Wendroff correction works by using the system of equations to express higher-order derivatives in time as spatial derivatives. The approximations of the higher-order time derivatives can be used to construct correction terms to cancel errors of successively higher order. Using the system

Numerical Methods, Finite Difference, Fig. 4 Dispersion curves for a $O(2,6)$ FD Scheme. A perfect solution should be equal to one. The dispersion curves vary depending on the ratio of the velocity of the medium and the maximum velocity used to determine the time step, that is, the (normalized) Courant number displayed in the legend. To yield a sufficiently accurate solution, this scheme should probably not be run with less than five to seven gridpoints per minimum wavelength (0.14–0.2 wavelengths/gridpoint)

$$\begin{cases} \frac{\partial p}{\partial t} = -\kappa \frac{\partial v}{\partial x} \\ \frac{\partial v}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \end{cases} \quad (8)$$

the corresponding Lax–Wendroff correction for a third-order time derivative is:

$$\frac{\partial^3 p}{\partial t^3} = \kappa \frac{\partial^3 v}{\partial x \partial t^2} = \kappa \frac{\partial}{\partial x} \frac{1}{\rho} \frac{\partial^2 p}{\partial x \partial t} = \kappa \frac{\partial}{\partial x} \frac{1}{\rho} \frac{\partial}{\partial x} \kappa \frac{\partial v}{\partial x}. \quad (9)$$

However, the method is somewhat cumbersome in multi-dimensions as it requires mixed derivatives and also derivatives of the material parameters, that is, ρ and κ in Eqs. 8 and 9 (see for instance Blanch and Robertsson (1997) for applications of the Lax–Wendroff correction).

The FD stencil can also be adjusted such that it is optimal for a certain frequency/wavelength range and thus achieves a higher accuracy than a standard scheme (Holberg 1987; Geller and Takeuchi 1995; Zingg 2000). Note that in a strict (and in this case misleading) Taylor sense, these schemes do not necessarily appear to be high-order schemes.

Fornberg (1987) noted that spatial and temporal dispersion can be considered as separate issues that can be minimized separately. Dispersion associated with the approximation of the time derivatives is not a function of the propagation path or type (e.g., P or S) of the synthesized data but only of the number of time-steps in the simulation since the source was introduced and can therefore be completely removed from FD computed data with a pre- and post-processing filtering procedure (Stork 2013; Koene et al. 2018). The computational

cost of obtaining this spectral accuracy in time is negligible. It can also be used in combination with Lax–Wendroff related schemes (e.g., Amundsen and Pedersen 2017) which generally also allow for larger time-steps without violating the stability condition of the FD scheme. Thus, stability may be increased without increasing time dispersion.

Time Stepping and Stability

As discussed above, the time stepping is most commonly explicit using a second-order approximation resulting in a leap-frog scheme. The explicit time stepping introduces a so-called CFL (Courant–Friedrich–Levy) stability condition prescribing the maximum size of the time step Δt . The CFL condition can be derived from the same Fourier transformation as described above (in the context of numerical dispersion) and requiring the resulting difference equation to have roots of absolute value less than or equal to one. As a result, the maximum time step is determined by the fastest wave speed in a medium, the spatial step, and a constant depending on the particular FD approximations used:

$$\Delta t \leq \frac{K}{\sqrt{D}} \frac{\Delta x}{c_{\max}}, \quad (10)$$

where the constant K depends on the spatial accuracy and is slowly decreasing with increasing accuracy of the scheme from a value of 1 for an $O(2,2)$ scheme, D is the dimension of the simulation (e.g., $D = 2$ for 2D) and $c_{\max}$ is the maximum wave propagation speed in the medium. Rapid changes

in material parameters may require an even smaller time step, but do not, in general, cause problems (Haney 2007). Using a temporal step larger than determined by the CFL condition yields an unstable simulation, that is, parasitic solutions will grow at an exponential rate and swamp the physical solution.

The Courant number is often used in the context of discussing stability and numerical dispersion. It is defined as

$$\gamma = c_0 \frac{\Delta t}{\Delta x}, \quad (11)$$

where c_0 is the local velocity of the medium. The Courant number can be interpreted physically as the fraction of the spatial increment that a wave can advance in a time step. From Eq. 11, we see that the Courant number controls the stability of the numerical scheme. In a heterogeneous medium, there exists a large range of velocities and it is thus important to study a FD scheme's behavior (i.e., numerical dispersion) for a range of Courant numbers (e.g., see Fig. 4). In the literature, the normalized Courant number is often used:

$$\gamma_{norm} = c_0 \frac{\Delta t}{\Delta x} \frac{\sqrt{D}}{K}, \quad (12)$$

which needs to be less than or equal to 1 for a stable simulation.

Amundsen and Pedersen (2017) showed that through a Lax-Wendroff related procedure it is possible to choose time steps that can be doubled, tripled, or generally, n -tupled beyond the classical CFL limit. However, like the Lax-Wendroff procedure, they require more computational effort per time step.

Boundary Conditions

The most important boundary conditions for wave simulations are radiating and free-surface boundary conditions. Radiating boundary conditions are applied at the edge of the finite computational domain to annihilate undesired reflections from the edge of the domain. The radiating boundary conditions can be implemented as “one-way” wave equation propagators using special operators at the boundaries. A first-order simple version is to implement the following equation at the boundary:

$$\frac{\partial p}{\partial t} = \pm c_0 \frac{\partial p}{\partial x}, \quad (13)$$

where the sign depends on which boundary (maximum or minimum x coordinate) and c_0 is the (local) propagation velocity. For a single propagation velocity, Eq. 13 is fairly straightforward to implement. However, significant complications arise for elastic or anisotropic media and for higher dimensions than 1D where it is the apparent velocity

perpendicular to the boundary that is the relevant parameter (Clayton and Engquist 1977; Higdon 1986, 1990).

The radiating boundary conditions are more commonly implemented as absorbing (or attenuating) boundary conditions applied in a finite region just inside the computational domain (Cerjan et al. 1985). Absorbing boundaries do, however, need to have a transition zone, where the attenuation of the wavefield is gradually increased, since a rapid change in attenuation will cause reflections as well. A particularly efficient absorbing boundary condition is the “Perfectly Matched Layer” (PML) (Bérenger 1994; Collino and Tsogka 2001). The PML allows the attenuation to be increased extremely rapidly without causing reflections. The PML boundary conditions can be thought of as introducing artificial anisotropy to the boundary and matching the reflection coefficient in different propagation directions. The most straightforward realization of a PML boundary is through the split-field technique, where the wavefield is split depending on which spatial derivatives are used to update it. For the system in Eq. 8 in two dimensions, an implementation for the p variable would be

$$\begin{cases} \frac{\partial p_x}{\partial t} + \beta_x p = -K \frac{\partial v_x}{\partial x} \\ \frac{\partial p_z}{\partial t} + \beta_z p = -K \frac{\partial v_z}{\partial z} \\ p = p_x + p_z \end{cases} \quad (14)$$

The coefficients β_i control the attenuation in either the x or z directions independently.

The straightforward split-field implementation is equivalent to a fully anisotropic implementation (Teixeira et al. 2002) but suffers from a mild instability for waves impinging on the boundary at an incidence angle higher than 45° . A slightly more complex implementation avoids this instability (Bécache et al. 2002).

The free-surface boundary condition is used to approximate the interface between a water/solid material and air. Since the acoustic impedance of air is significantly different from that of water or the Earth, explicit modeling results in a computationally much more expensive simulation. In fact, it is possible to use a (pressure release) free-surface condition instead (water or Earth in contact with vacuum). For a water/air contact it is simply implemented through mirroring,

$$\begin{cases} p(-z) = -p(z) \\ v_z(-z) = v_z(z) \end{cases}, \quad (15)$$

assuming the boundary is located at $z = 0$. The upper boundary in Fig. 2 is implemented using a free-surface condition. The free-surface condition for a solid elastic material is more complicated and cannot be achieved solely through mirroring. Care must be taken to ensure that all wavefield components satisfy the wave equation and the free-surface condition in

order to accurately model wave phenomena such as Rayleigh waves at the free surface (see Robertsson 1996, for details).

Topography and Conformal Mapping of Grids

Topography can either be implemented explicitly into a FD scheme (Robertsson 1996) or by stretching the grid through conformal mapping of the regular computational grid onto a grid with continuously varying grid spacings where the top of the grid follows the topography (Fornberg 1988; Hestholm and Ruud 1994). The explicit method will lose some of its flexibility to implement rapidly varying topography if a higher-order scheme is used for the solution. If a conformal mapping is used, all derivatives will depend on the mapping function through the chain-rule. This may lead to stricter stability conditions and stricter requirements on spatial sampling.

Source Implementations

Seismic sources can be introduced in terms of body forces as indicated in Eq. 1 or as moment-tensor sources using an equivalent source term in the constitutive equation (e.g., Eqs. 2 or 5). A straightforward approach is to simply drive a body force at one point by feeding Eq. 1 with the value of a desired source wavelet in a single spatial grid point at each time step. Although this approach tends to work fairly well, researchers have sometimes reported on high-frequency noise being introduced. The origin of this noise has been attributed to the intrinsic difficulty in representing delta functions on a discretely sampled model with continuous wavefields.

Practitioners in exploration seismology often mimic explosive sources by equal excitation of the diagonal elements of the stress tensor at the source location or alternatively model compressional or shear vibroseis source by either exciting vertical or horizontal body forces. Earthquake seismologists who wish to model a moment-tensor source can do this either through a stress or body-force representation as described by Moczo et al. (2007).

An alternative way to introduce a source wavefield on a FD grid is by means of a boundary condition on an artificial surface interior to the grid. The method was first described by Alterman and Karal (1968) and followed by many authors clarifying the concept (Kelly et al. 1976; Levander 1989; Robertsson and Chapman 2000; Moczo et al. 2007). The technique relies on two prerequisites. First, that the spatial FD operators have a limited extent in space and second, that the (isolated) source wavefield can be computed in a region around the source location without reverberations from the rest of the model at the (simulated) time of source insertion.

The method of introducing a source wavefield as a boundary condition along an internal surface can also be used in seismic data processing and imaging applications (e.g.,

Amundsen and Robertsson 2014) and in so-called hybrid methods where two different numerical solutions are coupled together (e.g., Robertsson et al. 1996; Zahradník and Moczo 1996; Robertsson and Chapman 2000; van Manen et al. 2007). However, the wavefield on opposite sides of the artificial surface in the technique above is reversed so that the source wavefield is present inside the artificial surface only.

Finally, Robertsson et al. (2015) showed that by introducing a source wavefield as a boundary condition, it is possible to output up- and down-going as well as P- and S-wave constituents to machine precision accuracy. This enables the use of FD methods in research where such outputs are required instead of relying on so-called propagator matrix methods that are limited to 1D media.

Conclusions

We have outlined the basic principles of FD approximations to the systems of first-order partial-differential equations describing acoustic, isotropic elastic, anisotropic elastic, or viscoacoustic/elastic wave propagation. The method is based on explicit leap-frog time-stepping and staggered-grid representations. Most commonly Taylor-series-derived stencils are used to approximate the spatial derivatives, although other means to optimize FD stencils have also been described.

Two types of boundary conditions exist. First, radiating or absorbing boundary conditions (e.g., PML) are used to truncate the model while avoiding boundary reflections. Second, a free-surface boundary condition can be used to simulate the surface of the Earth with or without topography.

Sources are introduced either as point-force or stress sources, or along closed (artificial) surfaces inside the FD grid.

The maximum possible spatial grid size in order to limit numerical error is computed from the slowest propagation velocity in the model (e.g., a shear-wave velocity in the near-surface) using the so-called numerical dispersion relation for the FD scheme. Once the grid spacing has been chosen, the maximum possible time step is computed from the CFL-stability condition. The maximum possible time step is proportional to the spatial grid size and inversely proportional to the maximum propagation velocity in the grid. Since the computational cost of a 3D FD simulation increases to the power of four with a linear reduction of grid size, high-order accurate FD stencils are usually preferred.

Numerical Methods, Finite Element

J. N. Reddy
Department of Mechanical Engineering, Texas A&M
University, College Station, TX, USA

Definition

The finite element method is a numerical method, like the finite difference method, for solving differential equations arising in the study of physical phenomena. In the finite

element method, a given domain is viewed as a set of non-intersecting subdomains, called *finite elements*, and over each element the governing equation is approximated by any of the traditional variational methods (e.g., Ritz, Galerkin, and least-squares methods). The main reason behind seeking approximate solution on a set of elements is the fact that it is easier to represent a complicated function as a sum of simple polynomials. Of course, each individual segment of the solution should fit with its neighbors in the sense that the function and possibly its derivatives up to a chosen order are continuous along the interface between elements. This entry is a brief introduction to the finite element modeling of diffusion processes and the Navier–Stokes equations governing viscous incompressible fluids. Both phenomena play crucial role in modeling a variety of geological or geomechanics processes.

General Introduction

Scientists and engineers model (i.e., develop mathematical models and numerically simulate) natural phenomena with the objective of understanding it. Virtually every phenomenon in nature, whether aerospace, biological, chemical, geological, or mechanical, can be described in terms of algebraic, differential, and/or integral equations relating various quantities of interest. Determining the stress distribution in a mechanical structure with oddly shaped members and numerous stiffeners and subjected to mechanical, thermal, and/or aerodynamic loads, finding the concentration of pollutants in lakes and estuaries or in the atmosphere, predicting geophysical and geological events, and simulating weather in an attempt to predict the formation of tornadoes and thunderstorms are a few examples of many important practical problems that scientists and engineers are occupied with.

In the last four decades, the finite element method has emerged as a powerful computational tool for solving non-linear partial differential equations over irregular domains with complex domain properties (Reddy 2015, 2019; Reddy and Gartling 2010; Bathe 1996; Belytschko et al. 2000). Applications of the method to geology, geophysics, and geomechanics problems are numerous (see, e.g., Reddy et al. 1982; Wickham et al. 1982; Bird 1989; Parsons 2002; Dyksterhuis et al. 2005 and references therein). This brief introduction is meant to provide some insight into the workings of the finite element method as applied to the Poisson equation as well as the Navier–Stokes equations that are used to model certain geomechanics processes in two dimensions.

Finite Element Model of 2-D Poisson Equation

Consider the problem of finding $u(x, y)$ such that the following partial differential equation (a generalized Poisson's equation) is satisfied

$$-\left[\frac{\partial}{\partial x}\left(a_{xx}\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(a_{yy}\frac{\partial u}{\partial y}\right)\right] = f(x, y) \text{ in } \Omega \quad (1)$$

where Ω is a two-dimensional domain with boundary Γ . Here a_{xx} and a_{yy} are material coefficients in the x and y directions, respectively, and $f(x, y)$ is the known source. For example, in a ground water flow problem u denotes the water head (i.e., velocity potential), a_{xx} and a_{yy} are the permeabilities in the x and y directions, respectively, and $f(x, y)$ is distributed water source. Equation 1 also arises in many areas of science and engineering.

In the finite element method, the domain $\bar{\Omega} = \Omega \cup \Gamma$ is divided into a set of subdomains $\bar{\Omega}^e = \Omega^e \cup \Gamma^e$, called finite elements. Any geometric shape qualifies as an element, provided that the approximation functions ψ_i^e can be derived uniquely for the shape.

Suppose that the dependent unknown u is approximated over a typical finite element $\bar{\Omega}^e$ by the expression

$$u(\mathbf{x}) \approx u_h^e(\mathbf{x}) = \sum_{j=1}^n u_j^e \psi_j^e(\mathbf{x}), \mathbf{x} = (x, y) \in \bar{\Omega}^e \quad (2)$$

where $u_h^e(\mathbf{x})$ represents an approximation of $u(\mathbf{x})$ over the element $\bar{\Omega}^e$, parameters u_j^e denote the values of the function $u_h^e(\mathbf{x})$ at a selected number of points (i.e., element nodes) in the element $\bar{\Omega}^e$, and ψ_j^e are the Lagrange interpolation functions associated with the element.

We seek to satisfy the governing differential equation in a weak-form sense, with the weight functions being the same as the approximation functions. The resulting finite element model, i.e., set of algebraic equations) is called the *weak-form Galerkin finite element model* (Reddy 2019). The weak form is

$$0 = \int_{\Omega^e} \left(a_{xx} \frac{\partial w_i^e}{\partial x} \frac{\partial u_h^e}{\partial x} + a_{yy} \frac{\partial w_i^e}{\partial y} \frac{\partial u_h^e}{\partial y} - w_i^e f \right) dx dy - \oint_{\Gamma^e} w_i^e q_n ds \quad (3)$$

Suppose that u_h^e is represented over a typical finite element Ω^e by expression of the form 2. Substituting the finite element approximation 2 into the weak form 3, we obtain

$$\mathbf{K}^e \mathbf{u}^e = \mathbf{f}^e + \mathbf{q}^e \equiv \mathbf{F}^e \quad (4)$$

where the coefficients K_{ij}^e , f_i^e and q_i^e are defined by

$$\begin{aligned}
K_{ij}^e &= \int_{\Omega^e} \left(a_{xx} \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + a_{yy} \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) dA \\
&+ \oint_{\Gamma^e} h_c \psi_i^e \psi_j^e ds \\
f_i^e &= \int_{\Omega^e} f \psi_i^e dA, q_i^e = \int_{\Gamma^e} (\hat{q}_n + h_c u_c) \psi_i^e ds
\end{aligned} \quad (5)$$

We note that $K_{ij}^e = K_{ji}^e$ (i.e., $\mathbf{K}^e$ is symmetric).

Finite Element Models of the 2-D Navier–Stokes Equations

In this section, we develop the finite element models of steady flows of viscous, incompressible fluids in two-dimensional domains. The governing equations are the conservation of linear momentum and conservation of mass, expressed in terms of the Cartesian components

$$\rho \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) - \frac{\partial \sigma_{xx}}{\partial x} - \frac{\partial \sigma_{xy}}{\partial y} - f_x = 0 \quad (6)$$

$$\rho \left(u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} \right) - \frac{\partial \sigma_{xy}}{\partial x} - \frac{\partial \sigma_{yy}}{\partial y} - f_y = 0 \quad (7)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (8)$$

$$\begin{aligned}
\sigma_{xx} &= 2\mu \frac{\partial u}{\partial x} - P, \sigma_{yy} = 2\mu \frac{\partial v}{\partial y} - P, \\
\sigma_{xy} &= \mu \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)
\end{aligned} \quad (9)$$

Here we present two different finite element models associated with Eqs. 6, 7, 8, and 9. The first one is a direct formulation in which the three equations in (u, v, P) are used in their original form. This formulation is known as the *velocity–pressure formulation*. The other formulation is based on the interpretation that the continuity equation (Eq. 8) is a constraint on u and v , and the constraint is satisfied in a least-squares (i.e., approximate) sense. This particular method of including the constraint in the formulation is known as the *penalty function method*, and the model is termed as the *penalty-finite element model*. It is informative to note that the velocity–pressure formulation is the same as the Lagrange multiplier formulation, wherein the constraint is included by means of the Lagrange multiplier. The Lagrange multiplier turns out to be the negative of the pressure.

Velocity–Pressure (Mixed) Model

The weak forms of Eqs. 6, 7, and 8 over an element Ω^e can be constructed following the standard procedure (Reddy 2015). The weight functions have the following physical interpretation:

$$w_1 \sim u, w_2 \sim v \text{ and } w_3 \sim -P \quad (10)$$

Assuming approximations of the form

$$u = \sum_{j=1}^m v_j \psi_j^e, \quad v = \sum_{j=1}^m v_j \psi_j^e, \quad P = \sum_{j=1}^n P_j \phi_j^e \quad (11)$$

where ψ_j^e and ϕ_j^e denote the Lagrange type interpolation functions ($n < m; n + 1 = m$) and substituting into the weak forms of Eqs. 6, 7, and 8, we obtain the following finite element model:

$$\begin{bmatrix} \mathbf{K}^{11} & \mathbf{K}^{12} & \mathbf{K}^{13} \\ \mathbf{K}^{21} & \mathbf{K}^{22} & \mathbf{K}^{23} \\ \mathbf{K}^{31} & \mathbf{K}^{32} & \mathbf{K}^{33} \end{bmatrix} \begin{Bmatrix} \mathbf{u} \\ \mathbf{v} \\ \mathbf{P} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^1 \\ \mathbf{F}^2 \\ \mathbf{F}^3 \end{Bmatrix} \quad (12)$$

where $F_i^3 = 0$

$$\begin{aligned}
K_{ij}^{11} &= \int_{\Omega^e} \left[\mu \left(2 \frac{\partial \psi_i}{\partial x} \frac{\partial \psi_j}{\partial x} + \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i \left(u \frac{\partial \psi_j}{\partial x} + v \frac{\partial \psi_j}{\partial y} \right) \right] dx dy \\
K_{ij}^{12} &= \int_{\Omega^e} \mu \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial x} dx dy, \\
K_{ij}^{13} &= - \int_{\Omega^e} \frac{\partial \psi_i}{\partial x} \psi_j dx dy, \quad K_{ij}^{33} = 0 \\
K_{ij}^{22} &= \int_{\Omega^e} \left[\mu \left(\frac{\partial \psi_i}{\partial x} \frac{\partial \psi_j}{\partial x} + 2 \frac{\partial \psi_i}{\partial y} \frac{\partial \psi_j}{\partial y} \right) \right. \\
&\quad \left. + \rho \psi_i \left(u \frac{\partial \psi_j}{\partial x} + v \frac{\partial \psi_j}{\partial y} \right) \right] dx dy \\
K_{ij}^{23} &= - \int_{\Omega^e} \frac{\partial \psi_i}{\partial y} \psi_j dx dy, \quad K_{ij}^{21} = K_{ji}^{21}, \\
K_{ij}^{31} &= K_{ji}^{13}, \quad K_{ij}^{32} = K_{ji}^{23} \\
F_i^1 &= \int_{\Omega^e} f_x \psi_i dx dy + \oint_{\Gamma^e} t_x \psi_i ds, \\
F_i^2 &= \int_{\Omega^e} f_y \psi_i dx dy + \oint_{\Gamma^e} t_y \psi_i ds
\end{aligned} \quad (13)$$

Here (t_x, t_y) denote the components of the stress vector $\mathbf{t}$ on the boundary

$$t_x = \sigma_{xx} n_x + \sigma_{xy} n_y, \quad t_y = \sigma_{xy} n_x + \sigma_{yy} n_y \quad (14)$$

and (n_x, n_y) are the components of the unit normal vector $\hat{\mathbf{n}}$.

Penalty-Finite Element Model

Use of the penalty function method amounts to replacing the pressure with

$$P = -\gamma \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \quad (15)$$

where γ is known as the penalty parameter. For complete details, the reader may consult (Reddy 2015, 2019; Reddy and Gartling 2010). Note that Eq. 15 is used to post-compute P once the velocity field is available.

Assuming interpolation of the form

$$u = \sum_{j=1}^n u_j^e \psi_j^e, \quad v = \sum_{j=1}^n v_j^e \psi_j^e \quad (16)$$

where ψ_i^e are Lagrange interpolation functions. Substituting Eq. 16 into the weak forms of Eqs. 6 and 7, we obtain the finite element model

$$\begin{bmatrix} \mathbf{K}^{11} & \mathbf{K}^{12} \\ \mathbf{K}^{21} & \mathbf{K}^{22} \end{bmatrix} \begin{Bmatrix} \mathbf{u} \\ \mathbf{v} \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^1 \\ \mathbf{F}^2 \end{Bmatrix} \quad (17)$$

where

$$\begin{aligned} K_{ij}^{11} &= \int_{\Omega^e} \left[\mu \left(2 \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) \right. \\ &\quad \left. + \rho \psi_i^e \left(u \frac{\partial \psi_j^e}{\partial x} + v \frac{\partial \psi_j^e}{\partial y} \right) \right] dx dy + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} dx dy \\ K_{ij}^{12} &= \int_{\Omega^e} \mu \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial x} dx dy + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial y} dx dy \\ K_{ij}^{22} &= \int_{\Omega^e} \left[\mu \left(\frac{\partial \psi_i^e}{\partial x} \frac{\partial \psi_j^e}{\partial x} + 2 \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} \right) \right. \\ &\quad \left. + \rho \psi_i^e \left(u \frac{\partial \psi_j^e}{\partial x} + v \frac{\partial \psi_j^e}{\partial y} \right) \right] dx dy + \int_{\Omega^e} \gamma \frac{\partial \psi_i^e}{\partial y} \frac{\partial \psi_j^e}{\partial y} dx dy \\ F_i^1 &= \int_{\Omega^e} f_x \psi_i^e dx dy + \oint_{\Gamma^e} t_x \psi_i^e ds, \\ F_i^2 &= \int_{\Omega^e} f_y \psi_i^e dx dy + \oint_{\Gamma^e} t_y \psi_i^e ds \end{aligned} \quad (18)$$

The numerical evaluation of the coefficient matrices appearing in Eq. 17 requires special consideration. Eq. 17 is of the general form

$$(\mathbf{K}^\mu + \mathbf{K}^\rho + \mathbf{K}^\gamma) \Delta = \mathbf{F} \quad (19)$$

where $\mathbf{K}^\mu$, $\mathbf{K}^\rho$, and $\mathbf{K}^\gamma$ denote the contributions from the viscous, inertia, and penalty terms, respectively. In theory, as we increase the value of the penalty parameter γ , the conservation of mass is satisfied more exactly. However, in

practice, for some large value of γ , the contribution from the viscous and inertia terms would be negligibly small compared to the penalty terms in the computer. Thus, if $\mathbf{K}^3$ is a nonsingular (i.e., invertible) matrix, the solution of the final equations associated with Eq. 19 for a large value of γ is trivial

$$\lim_{\gamma \rightarrow 0} (\mathbf{K}^\mu + \mathbf{K}^\rho + \mathbf{K}^\gamma) \Delta = \mathbf{F} \rightarrow \mathbf{K}^\gamma \Delta = \frac{1}{\gamma} \mathbf{F} \quad (20)$$

which will yield $\Delta = 0$. While the trivial solution satisfies the continuity equation, it does not satisfy the momentum equations for nontrivial boundary data or body forces. In this case, the discrete problem (Eq. 17) is said to be over-constrained or “locked.” If $\mathbf{K}^\gamma$ is singular, then the sum $\mathbf{K}^\mu + \mathbf{K}^\rho + \mathbf{K}^\gamma$ is nonsingular (because $\mathbf{K}^\mu$ is nonsingular after the imposition of proper boundary conditions), and a nontrivial solution to the problem may be obtained.

The numerical problem described above is eliminated by proper evaluation of the integrals in $\mathbf{K}^\gamma$. It is found that if the coefficients of $\mathbf{K}^\gamma$ (i.e., penalty terms) are evaluated using a numerical integration rule of one order less than that required to integrate them exactly, the finite element equations (Eq. 17) will give acceptable solutions for the velocity field. This technique of under-integrating the penalty terms is known in the literature as *reduced (order) integration*. For example, if a linear rectangular element is used to approximate the velocity field in a two-dimensional problem, the matrix coefficients $\mathbf{K}^\mu$ as well as $\mathbf{K}^\rho$ are evaluated using the 2×2 Gauss quadrature, and $\mathbf{K}^\gamma$ are evaluated using the one-point 1×1 Gauss quadrature. The one-point quadrature yields a singular $\mathbf{K}^\gamma$. Therefore, Eq. 17 cannot be inverted, whereas $\mathbf{K}^\mu + \mathbf{K}^\rho + \mathbf{K}^\gamma$ is nonsingular and can be inverted (after assembly and imposition of boundary conditions) to obtain a good finite element solution of the original problem. When a quadratic rectangular element is used, the 3×3 Gauss quadrature is used to evaluate $\mathbf{K}^\mu$ and $\mathbf{K}^\rho$, and the 2×2 Gauss quadrature is used to evaluate $\mathbf{K}^\gamma$.

The choice of the penalty parameter is largely dictated by the ratio of the magnitude of penalty terms to the viscous and convective terms (or compared to the Reynolds number, Re), the mesh, and the word length in the computer. The following range of γ is suggested in computations

$$\gamma = 10^4 Re \text{ to } \gamma = 10^{12} Re.$$

Summary

Numerical simulation of geomechanical processes requires a good understanding of computational fluid mechanics, heat

transfer, and solid mechanics and their couplings. The increase in computing power in both single processor and parallel environments has allowed realistic geomechanics problems of significant complexity and fidelity to be routinely solved and utilized in technological advances. Commercial software has made rapid progress in providing a broad spectrum of analysis capabilities to a variety of industries. Though software is increasingly robust, accurate simulations still require a knowledgeable user, with a background in both mechanics and numerical methods. This entry only provides an introduction to an individual who is interested in the use of the finite element method as a numerical simulation tool for the study and understanding of geomechanical phenomena. The Poisson equation and the Navier–Stokes equations visited here provide the necessary background for the study of diffusion processes and viscous flow problems. Interested readers may consult the references listed.

Definition

A multigrid method is an algorithm for the iterative solution of partial differential equations using a sequence of discretizations on multiple scales.

Introduction

The numerical solution of a partial differential equation (PDE) requires its discretization and a method to solve the resulting large system of algebraic equations. For linear equations, the resulting system is often a sparse matrix, and a direct solution method suffices if the size of the problem is modest. In three space dimensions, the computational cost of a direct solver may be too high. An iterative method that improves the accuracy of an approximate solution step by step can be a good alternative. Multigrid is an example.

The multigrid method has optimal complexity: the amount of work required to solve a problem with N unknowns is $O(N)$, meaning that it scales with the problem size N . It achieves its efficiency by employing several discretization grids for the same problem.

History

Fedorenko (1964) introduced the multigrid method as an iterative scheme for solving Poisson's equation on a square and showed that the number of computations required to determine a solution with a prescribed accuracy is proportional to the number of unknowns, N . Therefore, the method has an optimal computational complexity. Brandt (1973) found that the actual computational cost for a sufficiently accurate result was about 10 work units, where a work unit is the cost of evaluating the discretized equations. He connected the method to local adaptive grid refinement and introduced nonlinear multigrid. Hackbush (1976, 1985) discovered the method independently and provided a mathematical foundation. Since then, the method was developed further to handle PDEs other than Poisson's, which is elliptic, and to go beyond PDEs.

Textbooks include those by Hackbush (1976), who includes convergence proofs; by Wesseling (1992), with chapters on computational fluid dynamics; by Briggs et al. (2000), an easy to read introduction; and by Trottenberg et al. (2001), among others.

Two-Grid Scheme

A discrete representation of a PDE provides an algebraic system of equations with relations between solution values at neighbouring grid points. It is fairly easy to make local corrections that reduce the solution error on a short range but much harder to correct the long-range or long-wavelength components of the solution that have a more global character. By projecting the solution onto a coarser grid, the long wavelengths become shorter and can effectively be solved for. Combining the corrections to the solution from coarser and finer grids yields an efficient solver.

A simple one-dimensional example can help to understand the fundamentals of the multigrid method. The PDE is $Lu = f$, with $u(x)$ the unknown solution as a function of position x on a finite interval $[x_{\min}, x_{\max}]$ on the real axis, $f(x)$ a source term or forcing function, and L a linear differential operator, for instance, minus the Laplacian, which in 1D is $-\frac{d^2}{dx^2}$. Dirichlet boundary conditions let the solution be zero at the endpoints of the interval. To obtain a discrete representation of the problem, an equidistant one-dimensional grid is defined with grid points $x_k = x_{\min} + kh$, index $k = 0, \dots, N+1$, where $N+1 = 2^M$ and M is a positive integer. The grid spacing is $h = (x_{\max} - x_{\min})/(N+1)$. A standard second-order finite-difference scheme leads to

$$\frac{-u_{k-1} + 2u_k - u_{k+1}}{h^2} = f_k, \quad k = 1, \dots, N,$$

where u_k approximates $u(x_k)$ and $f_k = f(x_k)$. At the boundaries, $u_0 = u_{N+1} = 0$. The discrete equations represent the problem $L^h u^h = f^h$, where L^h is a $N \times N$ sparse matrix and u^h and f^h are vectors of length N . The residual is defined as $r^h = f^h - L^h u^h$ and should vanish once the numerical solution has been found.

A simple iterative method is Jacobi relaxation, in which the matrix L^h is replaced by its diagonal $D^h = 2/h^2$. One step of Jacobi relaxation amounts to

$$u^h := u^h + \omega (D^h)^{-1} r^h.$$

The symbol “:=” indicates that the solution values are replaced by the expression on the right-hand side. The factor ω controls the amount of damping. Convergence requires $0 < \omega \leq 1$. Fourier analysis (Hackbush 1985) shows that the convergence rate, the factor by which the norm of the difference between the current and the exact numerical

solution is reduced, is $1 - O(h^2)$ for Jacobi relaxation. Convergence slows down on increasingly finer grids.

The Fourier analysis reveals that the slow convergence is caused by the long-wave components of the solution. Because long waves can be represented on coarser grids, it makes sense to have look at a two-grid scheme, outlined in Fig. 1 and its caption. The coarse grid consists of every other grid point of the fine grid: $x_K = x_0 + KH$, with $H = 2h$ and $K = 0, \dots, \frac{1}{2}(N+1)$. A restriction operator $\tilde{I}_h^H$ maps the current fine-grid residual r^h to the coarser grid: $r^H = \tilde{I}_h^H r^h$. The simplest restriction operator is injection: $r_K^H = r_{2K}^h$, $K = 1, \dots, \frac{1}{2}(N-1)$. Full weighting, which lets $r_K^H = \frac{1}{4}r_{2K-1}^h + \frac{1}{2}r_{2K}^h + \frac{1}{4}r_{2K+1}^h$, applies some smoothing to the residual and is more common. The exact solution of the coarse-grid problem yields the coarse-grid correction $v^H = (L^H)^{-1} r^H$, which should be interpolated back to the fine grid and added as a correction to the latest fine-grid solution. The interpolation or prolongation operator is denoted by I_H^h and lets $u^h := u^h + I_H^h v^H$.

If linear interpolation is used for prolongation, this becomes

$$u_{2K}^h := u_{2K}^h + v_K^H, \quad K = 1, \dots, \frac{1}{2}(N-1),$$

$$u_{2K-1}^h := u_{2K-1}^h + \frac{1}{2}(v_{K-1}^H + v_K^H), \quad K = 1, \dots, \frac{1}{2}(N+1).$$

Here, it is assumed that $v_0^H = v_{(N+1)/2}^H = 0$. After prolongation, an additional relaxation step with damped Jacobi further removes oscillatory error components of the solution. Jacobi relaxation inside this two-grid scheme has a different purpose than when used as an iterative solver by itself. Instead of removing both the short- and long-wave components of the numerical solution error, it only has to deal with those components that cannot be represented on the coarser grid without aliasing. Therefore, a damped version with $\omega < 1$ can be more effective as it can be optimized to remove the short-wave or oscillatory components. For Fig. 1, $\omega = 2/3$ was used. The optimal choice requires a more detailed analysis (Hackbush 1985).

A relaxation scheme geared towards removing oscillatory components is called a smoother. Another popular choice is Gauss-Seidel relaxation. The operator is then approximated by a lower or upper triangular matrix, which is easy to invert. The implementation of the scheme is similar to Jacobi, but the residual is evaluated with the most recent solution available. The result will depend on the order in which the grid is traversed. With lexicographic Gauss-Seidel, one follows the natural index k in increasing order or in the opposite direction. Symmetric Gauss-Seidel performs both these smoothing steps in sequence. An alternative is red-black Gauss-Seidel, where first the points with an odd and then those with an even

Numerical Methods, Multigrid, Fig. 1 Steps in a two-grid cycle. (a) The initial solution on the fine grid is set to zero and the residual equals the forcing function. The dash line represents the exact numerical solution. (b) After one step of pre-smoothing with damped Jacobi relaxation, the solution error is still large, and the residual has hardly changed in this example. Its restriction to the coarser grid (c) is solved exactly, using a coarse-grid version of the discrete differential operator.

The resulting correction to the fine-grid solution (d) is interpolated or prolonged back to the fine grid and added to the fine-grid solution (e). The error in the solution is now dominated by the short wavelengths and appears as an oscillatory function, which is reflected in the corresponding residual. A post-smoothing step (f) removes most of the solution error. Repeating the whole cycle will further reduce the error

index are updated, always using the latest solution values for the residual. In 2D, this would follow a checkerboard pattern.

The grid transfer operator, restriction and prolongation, should obey $m_p + m_r > 2m$ (Hackbush 1985) where $2m$ is the order of the differential equation and $m_p - 1$ is the highest degree of the polynomial that is interpolated exactly. The scaled adjoint of the restriction operator is an interpolation operator for which m_r can be defined in the same way as m_p . In the example above, $2m = 2$, full-weighting has $m_r = 2$, and prolongation based on linear interpolation has $m_p = 2$. More advanced grid transfer operators are based on the differential operator L^h , leading to operator-weighted restriction and prolongation.

The coarse-grid operator L^H can be based on the same discretization as the fine-grid operator L^h . An alternative is the Galerkin coarse-grid approximation $\tilde{I}_h^H L^h I_H^h$. In the current example with full weighting, these happen to be the same. Operator-weighted grid transfer operators can accelerate the convergence by using the coefficients of the differential operator in the construction of restriction and prolongation operators, which in turn will affect the Galerkin coarse-grid approximation of the differential operator.

Multigrid

Instead of using the exact numerical solution on the coarser of the two grids, a two-grid scheme can be applied to the coarse-grid problem. Extending this recursively to the coarsest grid

with three points and one unknown, a multigrid solver is obtained. All these grids can be visited in different orders. The standard approach is to start at the finest grid, perform a number of pre-smoothing steps, then move to the coarser grid, again perform pre-smoothing, and continue this until the coarsest grid is reached. There, the exact numerical solution is computed, and the resulting coarse-grid correction is prolonged back to the finer level, followed by a number of post-smoothing steps. This is repeated up to the finest grid. Such a sequence is called a V-cycle. A single V-cycle may be insufficient to obtain a convergence rate on the coarser grid that is similar to the smoothing rate on the finer grid. Convergence on coarser grids can be improved by performing more than one cycle. In the W-cycle, the number of cycles doubles on each coarser grid. Figure 2 illustrates the order in which grids are visited for a V-, W-, and F-cycle. The last one is less expensive than a W-cycle, as the number of cycles increases by only one for increasingly coarser grids. Another option, adaptive cycling, decides on the sequence of grids by monitoring the decrease of the residuals.

With a proper choice of relaxation scheme or smoother grid transfer operators, the multigrid method can reach a grid-independent or h -independent convergence rate. This does not, however, mean that the amount of work required to reach a sufficiently accurate solution is proportional to the number of grid points N . The exact numerical solution differs from the true solution of the PDE because of the numerical error due to the discretization, typically with some power p of h . In the earlier example, the discretization is second-order

Numerical Methods, Multigrid, Fig. 2 (a) V-cycle, (b) W-cycle, and (c) F-cycle

accurate, so $p = 2$. Given this numerical error, convergence to machine precision is more than needed. An iteration error somewhat smaller than the discretization error should suffice. Therefore, more iterations should be carried out if a more accurate solution on a finer grid has to be computed. This leads to an overall complexity of $O(N \log N)$ rather than $O(N)$. Successive grid refinement, in which one first computes a solution on a coarse grid and uses that as an initial guess for the next finer grid and so on, enables removal of the factor $\log N$, assuming that a fixed number of multigrid cycles are used at each level. The combination of successive grid refinement with a multigrid solver is called full multigrid (FMG).

Nonlinear Multigrid

One way to apply the multigrid method to nonlinear PDEs is the use of Newton's method. A multigrid solver is then applied to a linearization of the discretized nonlinear problem. Another approach is the use of the discretized nonlinear PDE inside the multigrid algorithm. This requires the full solution to be available on the coarser grids. In the example above, only corrections to the solution were represented on coarser grids. The full approximation scheme (FAS) is a reformulation of the multigrid method that includes the full solution (Brandt 1982). It requires a restriction of the full solution, $u^H = I_h^H u^h$, and of the coarse-grid forcing function, $f^H = L^H(I_h^H u^h) + \tilde{I}_h^H r^h$. The prolongation needs to be changed to $u^h := u^H + I_h^H(u^H - I_h^H u^h)$, where u^H is the sufficiently converged solution on the coarser grid and $I_h^H u^h$ the restriction of the latest fine-grid solution. The restriction operators for the residuals, $\tilde{I}_h^H$, and for the solution, I_h^H , do not have to be the same. Note that the coarse-grid problem, $L^H u^H = f^H$, can be interpreted in a different way: $L^H u^H = f^H = \tilde{I}_h^H f^h + \tau_{hH}^H$. The fine-to-coarse defect correction, $\tau_{hH}^H = L^H(I_h^H u^h) - \tilde{I}_h^H(L^h u^h)$, ensures that the coarse-grid equations maintain the accuracy of the fine-grid equations.

Nonlinear equations of the form $L^h(u^h) = f^h$ fit into this scheme. For $L^H(u^H)$, the same discretization scheme as on the fine grid can be adopted. Smoothing operators can be based on a local linearization of the residuals.

Generalizations

Multigrid is highly efficient for the solution of Poisson's equation on the square, discretized by the finite-difference method on a Cartesian grid. For other PDEs, describing convection, diffusion, waves, and flow, the method may be less easy to apply. The same is true for unstructured grids, for instance, based on triangles or tetrahedra. With suitable modifications and at the expense of additional code complexity, the multigrid method can still be the optimal approach. With unstructured grids, the coarser and finer grid are generally not nested, leading to grid transfer operations that are less easy to code than on a Cartesian grid.

Anisotropy in the PDE can degrade performance. Consider the equation:

$$-\frac{\partial^2 u}{\partial x^2} - a \frac{\partial^2 u}{\partial y^2} = f(x, y).$$

For $0 < a \ll 1$, smoothing operators may have difficulty with the y -direction where there is only weak coupling between neighbouring unknowns. Effective anisotropy in the discretized equation can also happen with grids that have widely different spacings in the various coordinate directions. A more powerful relaxation scheme may repair the poor performance of a simple smoother. For 2D problems, line relaxation will smooth in one direction and solve in the other. An example is line Jacobi relaxation, which approximates the matrix L^h by dropping the off-diagonals in one coordinate direction, while keeping them in the other. The dropped off-diagonals can be subtracted from the main diagonal with a suitable weight factor to obtain better smoothing properties. For 3D problems, plane relaxation is required, which may be too expensive. An alternative is semi-coarsening, where the coarse grid has the same number of points in the direction of weak coupling and is coarsened only in the direction in which the smoothing effectively removes the shorter wavelengths. Figure 3 shows an example of a grid before and after semi-coarsening in the horizontal direction. In the more general case where semi-coarsening is required in all coordinates, it can be applied in alternating directions.

Numerical Methods, Multigrid, Fig. 3 Semi-coarsening of grid (a) in the horizontal direction provides grid (b)

A more costly but powerful approach is simultaneous semi-coarsening in all coordinates (Mulder 1989), which still retains optimal complexity.

Beyond Partial Differential Equations

The application of the multigrid method is not restricted to the solution of PDEs. There are generalizations to eigenvalue problems, integral equations, optimization and optimal control, statistical physics, image processing, image segmentation, and edge detection. In all cases, the simultaneous use of different scales overcomes the problem of slowly converging solution components.

Algebraic multigrid (AMG), or, better, the algebraic multi-level method, refers to a class of solvers that construct sets of coarse-level equations without referring to grids or geometrical properties (Trottenberg et al. 2001; Shapira 2008). Coarsening is applied to subsets of unknowns for which smoothing is effective. If the problem is specified by a large matrix, these subsets can be determined by examining the coefficients of the matrix. Strongly coupled unknowns, say u_i and u_j , are related by a matrix coefficient a_{ij} that is relatively large. In that case, smoothing is effective, and one of the unknowns can be removed from the equations on the coarser level. The coarser level will then be mainly populated by weakly coupled variables. Operator-weighted grid transfer operators are natural in this context, as well as the Galerkin approach for the construction of the coarse-level operator. Algebraic multilevel methods are a popular choice for finite-element discretizations on unstructured grids, as they can be used as a black-box solver and do not require the tedious coding of grid transfer operations between non-nested elements.

The multigrid method bears some resemblance to other techniques such as wavelets, hierarchical-basis finite elements, multi-scale techniques, cyclic reduction, fast multipole methods, and other divide-and-conquer methods.

Geophysical Applications

Multigrid has been applied successfully to a wide range of partial differential equations, describing static and dynamic problems, diffusion, convection, and flow problems. Examples in geophysics include elliptic problems in potential theory, such as gravity (Kusche 2002), magnetostatics (De Giersem and Hameyer 2001), electrostatics (Ascher and Haber 2003), and Darcy's law in porous media flow (Mulder and Gmelig Meyling 1993). Two-dimensional phase unwrapping for satellite interferometric synthetic aperture radar (Pritt 1996) can also be stated as an elliptic problem. Controlled-source electromagnetics (Werthmüller et al. 2019), magnetotellurics (Li et al. 2015), mantle convection, and geodynamics (Gerya 2019) are examples of parabolic problems.

The wave equation for seismic applications is a hyperbolic problem. Iterative solution of its frequency-domain formulation, the Helmholtz equation, was a notoriously difficult numerical problem but can nowadays be accomplished by using a damped version as preconditioner in a conjugate-gradient-type iterative scheme. Multigrid efficiently deals with the approximate inversion of the preconditioner (Riyanti et al. 2006). In the generalization of the method to the elastic wave equation, simple Point-Jacobi smoothing turns out to be insufficient for the secondary or shear waves, and a more powerful smoother is required (Rizzuti and Mulder 2016).

Summary

The multigrid method provides an optimal iterative solution method for a wide class of problems governed by partial differential equations. Its application to a finite-difference discretization of Poisson's equation on a square is the easiest. For other problems, a bit more effort may be required.

Ocean bottom seismology

Introduction

Ocean bottom seismics, recording of seismic waves on the ocean floor by seismometers placed on the ocean floor, is becoming increasingly common both in academic research surveys and for hydrocarbon exploration. The main advantages of ocean bottom seismics over reflection seismics with hydrophone streamers (see ► [“Seismic Data Acquisition and Processing”](#)) are that the use of receivers on the seafloor yields sufficient source-receiver offsets to analyze the deeper crustal velocity structure, deploying multicomponent receivers allows recording of shear waves, and that instruments can be deployed for an extended time to record natural seismicity. In most cases, the seismic sources are either airguns towed on the sea surface or natural seismicity. Seafloor sources are rare.

Instrumentation

Seismic seafloor receivers fall broadly into three categories, (1) ocean bottom seismometers (OBSs), individual receivers that can be deployed and recovered without the need of any

specialized vessels, (2) ocean bottom cables (OBCs), streamer-like arrays of receivers that are deployed from a specialized vessel, and (3) ocean bottom seismic nodes, individual receivers that require underwater vehicles for deployment and retrieval.

Ocean Bottom Seismometers

OBSs are individual stations that contain sensors and electronics for data storage (Fig. 1). These instruments are deployed from a vessel, and descend to the seafloor weighted by an anchor. A release mechanism is activated toward the end of the survey, detaching the instrument from the anchor. The instrument then rises to the surface buoyed by flotation devices. The instrument is recovered onto the vessel where the recorded data are downloaded. The term ocean bottom seismometer is sometimes used for any instrument that records seismic waves at the seafloor, including OBCs and ocean bottom seismic nodes.

Communication with OBSs while on the seafloor is usually performed with acoustic transmission. This includes releasing the instrument from the anchor; although sometimes, a time-based release is used as backup in case communication fails. Acoustic communication is also used for determining the position of the instrument at the seafloor by triangulation and for checking the status of the instrument.

OBSs that contain only a hydrophone as receiver are often called ocean bottom hydrophones. Hydrophones record pressure waves in the water. Some instruments contain vertically oriented geophones, mostly in combination with hydrophones. But, more commonly used OBSs have 3-component geophones (one vertical, two horizontal components) or 4-component (4-C) OBSs that contain 3-component geophones and a hydrophone. The type of geophone varies, depending on application – usually 4.5 Hz geophones (geophones with a resonance frequency at 4.5 Hz) for active-source experiments. Broadband seismometers with varying frequency bands (with periods as low as several tens of seconds) are used for recording of natural seismicity.

Ocean Bottom Seismics,
Fig. 1 Ocean bottom
seismometer (instruments used by
IfM-Geomar, Kiel, Germany)

Ocean Bottom Seismics, Table 1 Specification of modern OBS

Recording channels	Min. 4 (hydrophone, 3-component seismometer) Optional additional channels for supplementary sensors (e.g., pressure, CH ₄ , temperature)
Sampling rate	20 Hz to 1 kHz (passive or active seismology)
Data capacity	Tens of GB with flash memory (lowest power) > 50 GB with low power disk drives
Time stability	GPS synchronized prior and after mission timing accuracy 0.05 ppm/0.03 ppm (2.6/4.3 ms/day; depending on power consumption)
Resolution	20 + bit, 32 bit ideally wanted (not yet available)
Power consumption	< 250 mW when active (depending on sensors)
Time of operation	Depending on battery supply up to 1 year
Release system	Acoustic release (optional with additional time release); burn wires, gradually replaced by motor-
Recovery aids	Radio beacon, flash light (optional flag, surface line)

In a few cases, accelerometers (measuring particle acceleration rather than velocity as in geophones) are used to record seismic waves.

Seismic data are recorded continuously. Storage media have evolved from analogue tapes to hard drives and flash drives. Exact time stamps from an internal clock are critical for OBS records. GPS time synchronization is completed before and after deployment. Modern high precision clocks keep the deviation as low as 0.05 ppm (4.3 ms/day). For active-source experiments, the records are split into receiver gathers using shot times, usually in SEG-Y format. Data processing varies widely depending on the application and resembles that of land data. Some peculiarities of OBS records include unknown receiver locations, unknown orientations of the horizontal components, and a lack of continuous GPS time stamps. Typical specifications of a modern OBS are listed in Table 1.

Until the 1990s active-source OBS surveys typically involved 10–50 OBSs deployed along a seismic transect. Spacing between instruments for a survey targeting the deeper crustal structure typically was between 5 and 20 km, allowing travelt ime analysis of wide-angle reflected and refracted arrivals. In the past decade, significant improvements in hardware and electronics have made instruments less expensive and shortened turnaround times. This has led to a number of experiments with considerably more OBSs allowing imaging of deep crustal structures and 3D travelt ime analysis (e.g., Kodaira et al. 2000; Morgan et al. 2002).

Advances in batteries and storage devices also make it possible to continuously record seismicity with OBSs for up to ~1 year. The use of additional batteries may extend this time window but even for frames and housing made of titanium, corrosion is a problem. Therefore a service recovery after ~1 year is good practice. Such passive- source experiments are becoming more common to study the earth’s deep

structure, subduction zones on regional scales, as well as seismically active local features such as mud volcanoes (Brueckmann et al. 2009). A combination of onshore and offshore seismological networks has shown to significantly improve the determination of near-shore hypocenters (Husen et al. 1999; Arroyo et al. 2009).

Ocean Bottom Cables

OBCs are densely spaced receivers attached to a cable. The cable is deployed from a vessel, usually a specialized ship (Fig. 2). Seismic data are transmitted along the cable to be recorded on the vessel. Typical receiver spacing is 25 m. Most modern cables are equipped with 4-C receivers. Cables are often dragged along the seafloor to achieve deployment in a

Ocean Bottom Seismics, Fig. 2 OBC acquisition. Part of the downgoing P-wave energy is converted upon reflection to upgoing S-wave energy. ϕ_{pi} : angle of incidence, downgoing P-wave. ϕ_{pp} : exit angle, reflected P-wave. ϕ_{ps} : exit angle, P-to-S converted wave. Ray angles according to Snell's Law, that is, $\phi_{pi} = \phi_{pp}$ and $\sin(\phi_{ps})/V_s = \sin(\phi_{pi})/V_p$

straight line. Some OBCs use geophones that are being pushed into the seafloor by remotely operated vehicles (ROVs) to improve coupling to the seafloor. OBCs may also be deployed in trenches to improve coupling and reduce noise, such as for the Life of Field experiment for longterm monitoring of the Valhall oil field, North Sea (Barkved and Kristiansen 2005).

OBCs allow imaging of the subsurface with similar coverage as surface-towed streamers. Furthermore, coupling between receivers and seafloor is generally far better than for OBSs partly because the mass of the recording equipment is much smaller, and partly because the deployment techniques for OBCs facilitate slight “burrowing” of cables into the seafloor. OBCs are widely used in the oil and gas exploration industry. The need for a specialized cable deployment vessel, however, normally makes OBCs prohibitively expensive for academic research to date.

Ocean Bottom Seismic Nodes

Ocean bottom seismic nodes are individual receivers with independent recording units – essentially, OBSs without anchors and flotation devices. They are typically deployed with ROVs making their deployment relatively expensive compared to OBSs. Nodes are often deployed to fill coverage gaps in OBC surveys, for example, in the immediate vicinity of platforms where it is unsafe to deploy OBCs (or OBSs). Nodes are often pushed into the seafloor, which potentially leads to improved receiver coupling (Caldwell 1999).

Ocean Bottom Seismic Sources

By far the majority of active-source OBS surveys use pressure waves generated by airguns towed behind a vessel, although some ocean bottom sources have been pioneered, mainly to generate shear waves.

Explosives have been used as sources at the seafloor for an experiment to record shear waves in boreholes during Ocean Drilling Program Leg 156 but because of the strong increase of shear (S-) wave velocity with depth beneath the seafloor, rays were bent away from the borehole and did not reach borehole receivers (Peacock et al. 1997).

Furthermore, environmental and health and safety concerns preclude large-scale use of seafloor explosives.

Imploding glass spheres are the source of the SEEBOSEIS system, for which glass spheres containing air at atmospheric pressure are punctured on the seafloor (Nguyen et al. 2009).

Shear-wave “sleds” are occasionally used to study the high-resolution shear-wave structure of the first few meters beneath the seafloor. One such system uses an electromagnetic coil to generate seismic shear energy at the seafloor. Receivers are dragged along the seafloor behind the source. This system has been used successfully, for example, to measure near-seafloor S-wave velocity offshore California (Huws et al. 2000).

Applications

P-Waves

OBSs have been used extensively in the last 4 decades to study the crustal structure beneath the seafloor (see ► “Deep Seismic Reflection and Refraction Profiling”) from P-wave traveltimes analysis. A typical survey, for example, for a transect across a subduction zone consists of 20+ instruments spaced between 5 and 20 km. Seismic shot lines with maximum offsets of often >100 km are acquired with a large ($\sim 4,000$ – $8,000$ cu-in = 65 – 130 l) airgun array. Often, a coincident seismic reflection profile is acquired with the shot vessel although, in order to avoid noise from previous shots to interfere with arrivals from deep targets, shot intervals for crustal OBS surveys should be much larger (~ 60 s, equivalent to 100 – 150 m shot spacing) than would be desired for reflection surveying (~ 15 s) (Christeson et al. 1996) (see ► “Single and Multichannel Seismics”).

Such a configuration typically allows recording of reflected and refracted arrivals down to the base of the crust as well as refracted waves through the upper mantle (Fig. 3). Records are similar to those from land surveys, albeit often at considerably higher signal-to-noise ratio, and receivers and shots are reversed; land crustal wide-angle surveys typically have sparse shot and dense receiver spacing, whereas marine OBS surveys have dense shot but sparse receiver spacing.

Data processing often only involves bandpass filtering and amplitude scaling. Typical sources of noise or data contamination include reverberations particularly on horizontal components, previous-shot noise, water-column multiples, and noise from underwater currents that may shake the instruments.

As for land surveys, data are often displayed using a reduced traveltimes ($t_{red} = t - x/v_{red}$, where t_{red} : reduced time, x : source-receiver offset, v_{red} : reduction velocity). The origin of arrivals is identified and their traveltimes are picked, followed by traveltimes analysis to determine seismic velocities (see ► “Traveltimes Tomography Using Controlled-Source Seismic Data”). The latter is performed based on ray-trace modeling (e.g., Zelt and Smith 1992). In the past

Ocean Bottom Seismics, Fig. 3 Example of an OBS record from offshore the Faeroe Islands with interpreted arrivals (after Eccles et al. 2009). (a) vertical component, (b) rotated radial component, (c) schematic ray paths. See text in chapter on converted waves for details on radial component. Reduction velocities 7 km/s for vertical component, 3.9 km/s for radial component. Arrivals P-waves: Pg: diving wave in the crust, PmP: reflection from the top of the mantle (Mohorovičić discontinuity). Converted S-waves: PPS: S-wave, converted upon transmission

from upgoing P-wave at basalt-sediment interface. Sg: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and diving as S-wave in the basaltic crust. SmS: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and reflected as S-wave at the top of the mantle. Sn: S-wave, converted upon transmission from downgoing P-wave at basalt-sediment interface and diving as S-wave in the mantle. Courtesy Jennifer Eccles (University of Auckland, New Zealand)

decade, traveltimes inversion has become common allowing better determination of the uncertainties and uniqueness of resulting velocity models (e.g., Korenaga et al. 2000). However, the uncertainty from potentially misinterpreting the origin of arrivals is difficult to quantify.

Coincident OBS and seismic reflection surveys are being used for high-resolution studies of the first few hundreds of meters beneath the seafloor, in particular to obtain velocity information in the gas-hydrate zone. Data analysis usually comprises joint analysis of reflected and refracted P-waves often with additional structural information from seismic reflection data (Hobro et al. 1998). Many of these experiments are designed to achieve 3D ray coverage, sometimes coincident with 3D seismic reflection data (Plaza-Faverola et al. 2010). OBS experiments designed for 3D traveltimes analysis have also become more common for surveys targeting the deeper crust (e.g., Morgan et al. 2002).

The increased availability of OBSs has also led to a number of surveys using OBSs with sufficiently dense spacing to allow imaging of deep crustal structures similar to seismic

reflection data (e.g., Kodaira et al. 2000). Advancements in wide-angle migration techniques are key toward successful imaging with OBSs (e.g., Talwani and Zelt 1998). Imaging using OBSs is also improved by increased reflection coverage by utilizing rays from seafloor multiples, that is, rays that are reflected at the seafloor and sea surface, often referred to as mirror imaging (e.g., Grion et al. 2007).

High-resolution (sub-seismic-wavelength) P-wave velocities have been extracted from OBS data using 1D full-waveform inversion techniques similar to those applied to multichannel reflection data (Korenaga et al. 1997). Increases in computing power now also allow 2D visco-acoustic full-waveform tomography (Sourbier et al. 2009a, 2009b) (see ▶ “Seismic, Waveform Modeling and Tomography”).

P-to-S Converted Waves

Identification of P-to-S converted (PS-) waves in horizontal-component records has led to a paradigm shift in ocean bottom seismics in the late 1990s and early 2000s by the use of OBCs for multicomponent seismic exploration (Fig. 2) (see

► “Energy Partitioning of Seismic Waves” and ► “Seismic Data Acquisition and Processing”). P-waves are generated on a shooting vessel. They are partly converted at layer interfaces to S-waves. Upgoing S-waves are then recorded with OBCs or sometimes, densely spaced OBSs. The most prominent PS-arrivals are usually arrivals that are converted from downgoing P-waves upon reflection to upgoing S-waves.

Processing sequences for PS-waves require additional steps compared to conventional P-wave seismic reflection data acquired with surface-towed streamers (Stewart et al. 2002). In particular, processing of PS-waves requires separation of P- and S-waves, a rotation of the horizontal components such that a maximum amount of energy is projected into a single component, the radial component, and various modifications to adjust for the asymmetry of the PS-raypaths. A key step of data analysis is the correlation of P- and PS-events. Once P- and PS-events from the same horizons have been identified, determination of the ratio of P-wave velocity (V_p) over S-wave velocity (V_s) is straight-forward (e.g., Granli et al. 1999).

Multicomponent PS-wave surveys are being conducted routinely by the exploration industry, chiefly with the following objectives:

Imaging through gas clouds	P-waves are attenuated significantly in gas-bearing layers, whereas S-waves are almost unaffected by gas. Converted-wave surveys often yield superior images of structures in and beneath gas-bearing sediments even though in many cases the downgoing P-wave still has to penetrate gas (Granli et al. 1999).
Fluid discrimination	Reflection strength of PS-waves is only marginally affected by the pore fill (through its effect on density). Therefore, flat spots, oil-water or gas-water contacts at the base of hydrocarbon reservoirs, which generate P-wave reflections, usually do not cause any noticeable PS-reflections (e.g., MacLeod et al. 1999). For the same reason, PS-waves may help establish whether high negative-polarity P-wave reflections (bright spots) are likely to be caused by gas in sediment pores.
Mapping of sand–shale interfaces	Sand and shale layers often have similar V_p and density, which leads to low P-wave reflectivity. However, because V_s in sands is usually considerably higher than in shales, sand–shale interfaces often cause strong P-to-S conversion and have been imaged successfully with PS-waves (e.g., MacLeod et al. 1999).
Lithology from V_p/V_s	$V_p - V_p/V_s$ crossplots may be employed to delineate between sands and shales and to

Fracture detection from shear-wave splitting

constrain the shale content of reservoir sands (Margrave et al. 1998). V_p/V_s may also allow to distinguish between different types of carbonates (Rafavich et al. 1984). Nearvertical fractures common, for example, in carbonate reservoirs, causes an azimuthal dependence of velocities, azimuthal anisotropy (see ► “Magnetic Anisotropy”). The propagation of S-waves that are polarized perpendicularly to fractures is slower than that of S-waves polarized parallelly to fractures. This leads to PS-waves being split into fast and slow waves, depending on the azimuth of the incoming P-wave, and allows determination of azimuth and magnitude of anisotropy, from which fracture orientation can be inferred (Gaiser et al. 2002).

In recent years, P-to-S converted waves have been utilized increasingly to study V_s in the Earth’s crust (e.g., Eccles et al. 2009). Unlike for hydrocarbon exploration, with the aim of imaging the sedimentary section with S-waves converted from P-waves upon reflection, studies of the deeper crust often analyze traveltimes of S-waves converted from downgoing P-waves upon transmission. The sediment-basalt interface on the North Atlantic margin between the UK and Iceland, for example, provided a conversion horizon to allow determination of V_s in the deeper crust (Fig. 3). $V_p - V_p/V_s$ crossplots allowed lithological conclusions indicating mixing between continental crust and mafic intrusions across the ocean-continent transition and the presence of sub-basalt sediments on the Faeroe Margin (Eccles et al. 2009).

Wide-Aperture (Wide-Azimuth) Studies

Wide-aperture studies are increasingly conducted in the hydrocarbon exploration for “undershooting” in order to illuminate the subsurface beneath features that are difficult to penetrate with seismic energy and/or exhibit prominent localized velocity anomalies, such as gas clouds or salt domes: Rays in wide-aperture surveys may bypass these features and reach deeper targets of interest. The length of seismic streamers towed behind the same vessel that tows the airgun sources may not be sufficient for wide-aperture studies. Seismic arrivals at wide apertures may be recorded with surface-towed streamers by using separate vessels for sources and receivers. Alternatively, receivers deployed at the seafloor may be used. An acquisition campaign partly aimed at obtaining wide-aperture data across the Atlantis Field in the deep-water Gulf of Mexico involved 900 ocean bottom seismic nodes (Barley and Summers 2007). 3D surveys with ocean bottom receivers also provide illumination of seismic targets from different azimuths (multi-azimuth surveys),

which allows analysis for azimuthal anisotropy and may improve image quality. Wide-aperture seismic in the hydrocarbon exploration industry is often acquired as part of “seismic-on-demand” 4D surveys over permanently installed seismic surveillance systems such as at the Valhall Field (Barley and Summers 2007 and references therein).

Passive-Source Seismology

The use of modern storage media has led to a decrease in power consumption and an increase of storage capacity allowing deployments of OBSs for several months to over a year to record natural seismicity (Fig. 4). Because of the lower frequencies of natural seismic sources usually, broadband geophones are used with a lower resonance frequency than the 4.5 Hz geophones typically used for active-source surveys. Both local seismicity and teleseismic events are being evaluated similarly to data from land-seismic records. Unlike for land data, however, receiver location and geophone orientation need to be established. Local noise conditions in the deep oceans vary significantly throughout the seasons, but in general, noise is higher than on well-placed land stations. In addition, the seismic waveforms are contaminated by water-column multiples.

A very different application of passive-source ocean bottom seismology is to measure seafloor compliance. Pressure variations from ocean waves (gravity or infragravity waves) are being transmitted into the seafloor. Seafloor compliance is the transfer function between pressure loading and seafloor deformation. This transfer function is determined as a function of frequency and depends largely on the subsurface shear modulus (Crawford et al. 1991). Pressure variations are typically recorded with differential pressure gauges, seafloor

deformation derived from acceleration measured with self-leveling gravimeters. The frequency range of the analyzed pressure variations depends largely on water depth – because of the dispersion of ocean-surface waves, short-period waves are not transmitted into deeper waters. The resolution of subsurface shear-modulus analyses from compliance measurements decreases with decreasing frequencies. As an example, the frequency range for studying gas-hydratebearing sediments at 1.3 km water depth and 2 km beneath the seafloor was 0.003–0.049 Hz (Willoughby et al. 2008).

Future Developments

One of the most significant challenges for autonomous OBSs is still the power supply. Both data loggers and storage media are becoming increasingly energy efficient. Together with new battery technology and further improvement of fuel cells, this is leading to reduction of weight and size of instrumentation. Some study areas may provide additional power sources, such as thermal energy. Weight and size reduction in modern instruments is achieved in most cases by installing all the components in a single glass sphere. On the other hand, glass spheres require increased service efforts and precautions compared to more robust, but larger and heavier titanium pressure casing.

The use of ocean bottom sensors in permanent ocean-floor observatories is likely to become more common. OBSs have already been installed for long-term monitoring at seafloor observatories (e.g., GEOSTAR, Beranzoli et al. 2003) and have been integrated in deployments for tsunami warning systems. These observatories generally have the capability of data transmission to shore. Regional studies usually require a deployment of an array of sensors distributed over an area of several square kilometers. Several seismic seafloor observatories have been established to study the seismogenic zone offshore of Japan and a network of 20 instruments is being developed as part of the Japanese Dense Oceanfloor Network System for Earthquakes and Tsunamis (Kaneda et al. 2009).

Combined seismic and electromagnetic field experiments are becoming more common as the combination of both methods is proving powerful for studying subsurface lithology (Constable and Srnka 2007 and references therein). Despite significant technical challenges, especially with contamination of electromagnetic signals from the seismic instrumentation, it is conceivable that future ocean bottom instruments will include sensors for both seismic and electromagnetic waves.

The use of OBCs and nodes for hydrocarbon exploration and field appraisal appears to have become a “mainstream” technique. While costs for deployments of either type of instruments are still high compared to conventional 3D streamer seismic, they need to be weighed against the risk of mispositioning considerably more expensive appraisal

Ocean Bottom Seismics, Fig. 4 Teleseismic event on array of broadband OBSs at ~74°N 17°E (between Norway and Spitsbergen), the Mw 7.9 Sichuan Earthquake (China), May 12, 2008. Courtesy Frank Krüger (University of Potsdam, Germany)

wells (Barley and Summers 2007). Furthermore, several hydrocarbon fields are now being monitored with permanent installation of ocean bottom sensors for repeat-seismic surveys in order to guide field development (Barley and Summers 2007 and references therein).

Conclusions

The last decade has seen a substantial increase of ocean bottom seismic studies. While seafloor seismic sources are rarely deployed, the use of seafloor seismic sensors has established itself primarily for recording offshore wide-angle data, P-to-S converted waves, and natural seismicity. Academic research surveys, for studying the deeper crustal structure, are usually conducted with autonomous OBSs, which are relatively inexpensive and versatile. Surveys by the exploration industry for evaluating and developing hydrocarbon reservoirs mostly involve deployment of ocean bottom cables or ocean bottom seismic nodes, which give superior data quality compared to OBSs but at much higher cost. In recent years, permanent deployment of instruments has become more common in ocean bottom observatories and for monitoring the development of hydrocarbon fields. The rapid development of ocean bottom seismic instruments is leading to improvements in reliability, data quality, and efficiency, which makes it likely that ocean bottom seismics will continue to expand significantly in the future.

Ocean, Spreading Center

K. S. Krishna

Centre for Earth, Ocean and Atmospheric Sciences,
University of Hyderabad, Hyderabad, India

Definition

The *spreading center*, also known as a segment of the mid-ocean ridge, is an underwater mountainous feature with a rift valley lying between the two lithospheric plates, through which new magma material being continuously spread out and led to construction of the lithospheric plates on either side.

The *ridge internal structure*, the partially melted mantle up welled through the mid-ocean ridge segments/spreading centers, forms a basaltic crust of 3–6 km thick, but at a later stage, the same crust moves away from the ridge crest and allows growth of mantle component.

Introduction

The rigid outer layer of the Earth comprising the crust and uppermost mantle (generally about 70–100 km thick below the oceans), *termed as oceanic lithosphere*, is divided into a number of tectonic plates. Presently there are about eight major tectonic plates, viz., North American, South American, African, Indian, Australian, Antarctica, Eurasian, and Pacific; seven minor and several more smaller plates are covering the Earth's surface (for details, see Wikipedia website: http://en.wikipedia.org/wiki/List_of_tectonic_plates). The lithospheric plates are bounded by one of the three main types of geologic features: (1) mid-oceanic ridges, (2) subduction zones, and (3) transform faults. The boundaries are narrow deforming zones and are associated with intense seismicity, whereas the plate's interiors are relatively stable. The plates, on which continents and ocean floor commonly lie, are in continuous motion at a speed of few centimeters per year. Each plate is in relative motion with respect to the other on the surface of the Earth. The relative motion produces new crust at mid-oceanic ridges and consumes old lithosphere at subduction zones. Apart from these tectonic processes, on large geologic framework, plates do undergo breakups and unifications.

Morphology and Spreading Rates of Mid-Oceanic Ridge

A mid-ocean ridge is an underwater linear physiographic feature and also serves as a divergent tectonic boundary between two lithospheric plates. The mid-ocean ridges are physically connected within the ocean and also with the ones lying in other oceans (Fig. 1). Thus, the ridge systems encircle the entire globe from one ocean to the other and extend for a total length of about 65,000 km as a single global entity (Fig. 1). Many of the major oceanic ridges in the world oceans have been reconfigured in the geologic past that led to unification and split of the lithospheric plates. One of the well-mapped ancient oceanic ridges in the Indian Ocean is the Wharton Ridge, once separated the Indian and Australian plates, and the ridge cessation at about 42 million years ago led to unification of both aforesaid plates into a single Indo-Australian plate (Liu et al. 1983; Krishna et al. 1995, 2012).

In deep-sea regions, long, linear, and elevated features with variable undulations are observed (Fig. 2). They are the locations where hot magma is continuously raising and being added to the previously formed oceanic lithosphere on either side of the spreading ridge system. The upwelling magma rates along the global mid-oceanic ridges are not fixed; they greatly vary with a range from 6 to 200 mm per year. Following the seafloor expansion rates, the mid-oceanic ridges are classified into categories of slow-, intermediate-, and fast-spreading ridges. The Gakkel mid-oceanic ridge located in the Arctic

Ocean, Spreading Center, Fig. 1 General map of the global oceans showing mid-oceanic ridge system, subduction zones, and major fracture zones (after Royer et al. 1989 and Müller et al. 1997). MAR indicates

Mid-Atlantic Ridge in the Atlantic Ocean. CR, CIR, SWIR, and SEIR represent Carlsberg Ridge, Central Indian Ridge, Southwest Indian Ridge, and Southeast Indian Ridge, respectively, in the Indian Ocean

Ocean between Greenland and Siberia (Fig. 1) is the slowest-spreading ridge in world oceans with an upwelling magma rate of about 6 mm per year. On the other hand, the East Pacific Rise, particularly in equatorial region, generates magma at the fastest rates up to 200 mm per year. The seafloor morphology on flanks of the mid-oceanic ridge is largely controlled by the rate of seafloor accretions. Fast-spreading rates contribute to generally smooth and flat seafloor surfaces in the vicinity of the ridge, while the slow-spreading rates add exceptionally rough surfaces. The slow-spreading ridges are generally marked in their crest parts by an axial valley, called rift valley, which is clearly distinguishable along the Carlsberg Ridge in northern Indian Ocean (Fig. 2). The ridge crest is strongly characterized by rugged topography, steep valley walls, and wide rift valley floor (Kamesh Raju et al. 2008). Further the long ridge segment is bisected by less known non-transform discontinuities, while the fast-spreading ridge systems such as East Pacific Rise in Southeast Pacific Ocean and East Scotia Ridge in South

Atlantic Ocean do have crest-shaped features over the ridge axis without manifestation of rift valleys.

Internal Structure of the Mid-Oceanic Ridge

Along the mid-ocean ridge system, the lithospheric plates do expand on either side of it, which eventually lead to a partial melting of upwelling mantle and to form a layer of basaltic crust 3–6 km thick. Close to the ridge crest, the lithosphere may consist of oceanic crust only, but at a later stage, the same crust moves away from the ridge crest and allows growth of mantle component due to thermal cooling. Both lithosphere and elastic plate thicken continuously with the growing age of the ocean floor until about 60 Ma; thereafter the lithosphere and elastic plate thickness remains roughly stable.

A seismic reflection section across the East Pacific Rise is shown in Fig. 3 (Detrick et al. 1987). It shows the presence of

Ocean, Spreading Center, Fig. 2 Seafloor image of the Carlsberg Ridge segments, northern Indian Ocean. (Inset) Maps a and b show the study area (shaded box) and cruise tracks over the segment of the Carlsberg Ridge. (The image is reproduced from Kamesh Raju et al. 2008)

strong cohesive reflections on both sides of the section with a kind of discontinuity in the middle. These reflections possibly mark the Moho boundary separating the crust from the mantle, whereas the reflections lying in a shallow depth show a top of crustal low-seismic-velocity zone (LVZ). Detrick et al. (1987) interpreted the top of the LVZ as the roof of an axial magma chamber (AMC) within the crust beneath the ridge axis. On either side of the chamber, the reflections are weaker and perhaps represent the frozen top of the magma chamber body (shown with arrows in Fig. 3). Also, the reflections from Moho boundary are absent below the magma chamber. A sketch of the interpreted seismic structure of the East Pacific Rise is presented in Fig. 4.

Below a few of mid-oceanic ridge segments, it is found that the size of the axial magma chamber is either small or absent altogether. For example, multichannel reflection experiment carried out on the Mid-Atlantic Ridge (Detrick et al. 1990) did not find evidences for the presence of intracrustal reflections associated with an axial magma chamber. Seismic experiments, in general, demonstrated that along slow-spreading ridges magma chambers are either absent or extremely short-lived, if at all they exist. The Southwest Indian Ridge, an ultraslow-spreading ridge is a classic example for demonstrating the migration of melt supply. Geophysical studies in close proximity of the Prince Edward FZ

revealed that the melt supply center has migrated and reduced magmatic activity after some time (Sato et al. 2013).

Seismic refraction experiments carried out on a ridge segment between 8° and 9°S of the Mid-Atlantic Ridge revealed largely a different seismic structure from that of the East Pacific Rise. Interestingly, an axial magma chamber is not traceable within the Mid-Atlantic Ridge crust. Velocity models of the Mid-Atlantic Ridge segment (Minshull et al. 2003) suggest a total thickness of the crust ranging from 6.5 to 10 km with individual layers 2 and 3 having thickness of approximately 3 and 5 km, respectively (Fig. 5). The velocity heterogeneities are much greater in layers 2A and 2B, ranging from 2.65 to 3.0 km/s and from 4.6 to 6.8 km/s, respectively, while the velocities in layer 3 are remarkably uniform.

Relationships Between Spreading Rate, Seismic Structure, and Ridge-Axis Morphology

Geophysical experiments over the global mid-oceanic ridges have led to the discovery of some explicit relationships between spreading rate, seismic structure, and ridge-axis morphology. Purdy et al. (1992) found that as full spreading rate decreases from 150 to 20 mm yr.⁻¹ the depth to the top of the axial low-seismic-velocity zone (LVZ) increases from ~1

Ocean, Spreading Center, Fig. 3 Seismic reflection cross section across the East Pacific Rise shows the internal structure of the oceanic crust beneath the ridge axis. AMC represents significant seismic signals reflected from the roof of an axial magma chamber. Solid arrows on

either side mark relatively weaker reflections, perhaps representing the frozen top of the magma chamber, away from the ridge axis. M indicates the Moho boundary. (The image is reproduced from Detrick et al. 1987)

Ocean, Spreading Center, Fig. 4 A sketch showing the crustal structure beneath the East Pacific Rise (Reproduced from Detrick et al. 1987)

to ~4 km. In another study, Minshull et al. (2003) established a relationship between crustal thickness and ridge-axis morphology at a constant spreading rate. The ridge segments having large crustal thicknesses are associated with rifted axial highs, whereas the segments with reduced crustal thickness have deep axial valleys.

Large-scale detachment faults are found to occur on slow- and ultraslow-spreading ridges. At the slow-spreading ridges, detachment faults tend to occur where local magma supply is relatively low, while at the ultraslow-spreading rates, they tend to occur where local magma supply is relatively high (Zhiteng et al. 2013). Resource explorations over the global mid-oceanic ridges have also proven that they are important locations for metallic mineral depositions (Rona 1980). In subsequent studies, Zhiteng et al. (2013) have found the useful relationship that the detachment faults are accompanied by hydrothermal activities. Recently, Suo et al. (2017),

by analyzing the data of spreading rate, bathymetry, gravity, and geochemical data along the Southwest Indian Ridge, established a weak positive trend between spreading rates and occurrences of hydrothermal sites, thereby inferring that the long-term heat supply is the first-order control on global distribution of hydrothermal activity.

Summary

A mid-ocean ridge, an underwater mountainous feature, extends for a length of about 65,000 km as a single continuous body in the global oceans. This serves as a window into the Earth's interior, through which magma is continuously upwelling and drives the lithospheric plates on either side in order to accommodate newly accreted crust. Many of the oceanic ridges in the world oceans have been abandoned in the geologic past

Ocean, Spreading Center, Fig. 5 Velocity-depth profiles (solid lines) beneath the Mid-Atlantic Ridge segment between 8 and 9°S. Shaded region marks the range of velocities for 0–7 Ma Atlantic oceanic crust (White et al. 1992). (The figure is reproduced from Minshull et al. 2003)

and led to resume the activity elsewhere either in the intra-oceanic or intracontinental plate regions. Partially melted mantle upwelled through the mid-ocean ridge forms a layer of basaltic crust 3–6 km thick, but at a later stage, the same crust moves away from the ridge crest and allows growth of mantle component. The upwelling magma rates along the mid-oceanic ridges, in general, control the internal structure. Fast-spreading ridge such as East Pacific Rise has an axial magma chamber (AMC) at a shallow depth within the crust, whereas beneath an intermediate-spreading ridge, the Mid-Atlantic Ridge, an axial magma chamber is not traceable. Geophysical experiments over the global mid-oceanic ridges have found some explicit relationships between spreading rate, seismic structure, and ridge-axis morphology.

Orogenic Belts

A. M. Celâl Şengör

Faculty of Mines, Department of Geology and Eurasia
Institute of Earth Sciences, Istanbul Technical University,
Istanbul, Turkey

Synonyms

Fold belt; Folded belt; Folded mountains; Orogen

Partial Synonyms

Mountain belt; Height Systems, Vertical Datums and Their Unification

Definition

An orogenic belt is a lithospheric structure that is formed by the collective work of any group of convergent plate margin processes (see ► “[Lithosphere, Continental](#)”, and ► “[Lithosphere, Mechanical Properties](#)”). Kober (1921, p. 21) suggested the term “orogen” to designate the orogenic belts and his term is now generally used. Although orogeny is derived from the ancient Greek *oros* (mountain) and *genesis* (birth), just as old rifts and taphrogens may no longer have any topographic expression because of tectonic and/or erosional events, some, especially old, orogenic belts may no longer appear as linear/arcuate mountain ranges for the same reasons. Their original height with respect to their surroundings can be gauged by their stratigraphically older contents, or metamorphically higher grade of their uplifted corpus plus trains of intermediate and felsic igneous intrusions they usually contain.

Introduction

Orogenic belts or orogens constitute one of the three main classes of lithospheric-scale structures resulting from differential motion of parts of the lithosphere (Figs. 1 and 2):

lithospheric convergence creates the orogens, just as lithospheric divergence creates taphrogens and lithospheric horizontal simple shear along subvertical planes creates keirogens (Figs. 1 and 2). However, at present, only 20.5% of the active plate boundaries show normal convergence and 21% normal divergence. Some 8% show pure dextral strike-slip and some 6% pure sinistral strike-slip. The remaining 58.5% display some deviation from the three end-members, with relative motion vector angles to boundary strikes varying between 0° and 67° (Fig. 3: Woodcock 1986). Plate boundaries have probably shown a similar behavior in the past, so only about half of all the orogens a geologist may encounter is likely to show normal shortening, although tectonic escape may add significant strike-slip into an orogenic architecture even when plate convergence is normal to the trench and/or collision front (see ► “[Plate Motions in Time: Inferences on Driving and Resisting Forces](#)” and ► “[Plates and Paleoreconstructions](#)”). It should also be borne in mind that in the past continental collisions at times eliminated significant lengths of subduction zones during the construction of supercontinents such as the late Palaeozoic Pangaea resulting in the diminution of orogenic activity leading to a global slowing down of plate motions and lowering sea-level.

Orogenic belts are major features of the lithosphere on which 98% of the world’s largest earthquakes occur (<https://>

Orogenic Belts, Fig. 1 Active orogens of the world in the framework of world’s active plate boundaries and plate boundary zones. The lettered black lines refer to the cross-sections displayed in Fig. 2

Orogenic Belts, Fig. 2 Selected true-scale cross-sections of various types of active orogenic belts in the world. All of the cross-sections have the same scale. (Modified from Şengör (1990a)). The locations of the cross-sections are shown in Fig. 1 Key to abbreviations: *A* Aar massif, *AA* Austroalpine nappes, *B* Bergell pluton, *D4* Djebel Akhdar, *E* Eocene (in A) and Engadine (in K), *EST* East Senghe Thrust, *G* Gotthard massif, *H* Helvetic nappes, *HD* Hamrat Duru ranges, *HW* Hawasina Window, *M* Molasse basin, *MBT* Main Boundary Thrust, *MCT* Main Central Thrust, *MHF* Main Himaladri Fault, *MR* Mediterranean Ridge, *N* Neogene, *NAF* North Anatolian Fault, *P* Pennine nappes, *Pz* Palaeozoic, *S4* Southern Alps, *T* Tavetsch massif, *Tz* Triassic

www.usgs.gov/faqs/where-do-earthquakes-occur; last visited on 12th December 2019). Out of these 81% alone occur along the Pacific rim, the so-called “Ring of Fire,” and 17% along the Alpine-Himalayan mountain ranges. About 1/3 of the world’s active volcanoes occur along the Ring of Fire (total of 452 volcanoes) and 1/6 of them along the Alpine-Himalayan mountains including Indonesia (total 216 volcanoes). Since the diameter of the Earth does not change to any appreciable degree, ocean-floor spreading and subduction must balance each other. Spreading occurs along an 80,000 km-long mid-oceanic ridge system, whereas subduction and postcollisional shortening occur along a 55,000 km long front along the active orogens of the world. Thus, the rate of total deformation along orogenic belts must be almost 1.5 times higher than along the spreading centers, which is corroborated by the concentration of the largest earthquakes along them making them the most active parts of the lithosphere.

Orogenic belts are the main factories of the continental crust, at least since after the Hadean. Because the Earth is the only planet in the Solar System with a continental crust, orogeny, that is, the making of orogenic belts, must be an essential part of any theory of the Earth. Orogens house the world’s main mineral wealth and an understanding of their nature is critical for successful mineral exploration. The basins flanking them and genetically associated with them

contain a significant portion of the world’s hydrocarbon resources. Knowing how they evolve is an indispensable part of oil and gas exploration on this planet. Finally, orogenic belts create mountains which control a good portion of the world’s climate and climate in turn partly controls the growth of mountain belts.

For good reviews of orogenic belts and orogeny, see Smith (1976), Dewey (1977, 1980, 2002, 2005), Johnson and Harley (2012), Miyashiro et al. (1982), Molnar (1986), Rodgers (1987, 1990, 1991, 1995, 1997), Şengör (1990a, 2006). For the timing question in orogenic belts, see Şengör (1991a and the references therein; Dewey 2005). This very inadequate list of references, imposed by the available space in an encyclopedia article that was synthesized from the publications of more than three hundred geologists, would lead the reader at least to some other sources discussing the detailed aspects of orogens and orogeny. The rest the reader can search in the internet using the concepts discussed herein as keywords.

The Orogenic Architecture

Figure 4 illustrates the main elements of orogens. The defining feature of an orogen is its subduction zone (Fig. 5) which is commonly lost after continental collision. Eduard Suess first emphasized in 1875 the fundamental asymmetry of

Orogenic Belts, Fig. 3 World plate boundary map, modified from Woodcock (1986) showing plate boundaries smoothed with respect to oceanic ridge-transform systems and are ornamented according to the

angle between the boundary and the local relative velocity vector (shown in the inset)

Orogenic Belts,

Fig. 4 Orogenic terminology illustrating the basic orogenic architecture. (a) A subduction-controlled shortening continental margin orogen such as the Andes. (b) An extensional subduction-controlled orogen such as the Marianas/Kyushu-Palau System. (c) A collisional orogen

Orogenic Belts, Fig. 5 Various subducting slabs from the world's subduction zones compiled from different sources. Note the great variability of the subduction angles, but the fixed position of the arc axis above a certain depth of the slab. Arrows indicate advance or retreat of the slab

Orogenic Belts, Fig. 6 Simplified cross-section across three types of subduction-related, magmatic arc orogens. (a) Shortening, (b) neutral, (c) extending; detail to the right of a, b and c show the schematic metamorphic isotherms in each

orogenic belts and distinguished forelands from hinterlands and external parts of orogens from their internal parts. The fundamental architectural elements in a convergent plate boundary is the *foreland*, made up of the subducting lithosphere, the *orogen*, the deformed edges of the converging plates with magmatism being confined mainly to the upper plate, and the little to undeformed parts of the overlying plate called the *hinterland*. Parts of an orogen closer to the foreland are called its *externides* and are commonly little metamorphosed and deformed, whereas those parts closer to the hinterland constitute the *internides* of an orogen characterized by intense metamorphism and deformation, which, however, dies out towards the more internal parts as the orogen merges with the hinterland. An orogen is said to *face* towards its foreland, that is, in the direction opposite to the dip direction of its formative subduction zone. Dominant vergence of orogenic structures is usually towards the foreland, towards which the main tectonic transport occurs, but this is not universally so.

Figure 4 shows the main architectural elements of subduction- and collision-controlled orogens. The subduction controlled-orogens (Fig. 6) may be shortening (Fig. 6a),

neutral (Fig. 6b) or extensional (Fig. 6c) type depending on the age of the subducting slab. Opinions about the effect of the age of the slab on creating extension arcs have been divided. While some argue that young slabs induce shortening, others have argued the opposite because of deep-mantle buckling of young slabs. Although collisional orogens (Fig. 4c) may have topography-induced secondary extension, wholesale extensional collapse of orogens commonly requires a different process, such as transtension or a switch from plate convergence to plate divergence, to interfere.

Subduction-Controlled Orogens

The fore-arc: In most subduction-controlled orogens, the formative subduction zone meets the overlying plate usually at a deep-sea trench (e.g., Fig. 2c; world's deepest point, the Challenger Deep, located at 11°22.4 N and 142°35.5 E, with a depth range of –10,902 to 10,929 m is in the Mariana Trench; also Fig. 2g, h); where such a trench is not present (e.g., Fig. 2d, E), it is a consequence of its overflowing with sediment as in the Makran case. The forward lip of the overlying plate in subduction-controlled orogens called the arc-trench gap or the fore-arc (Dickinson and Seeley 1979) may be

characterized by a subduction-accretion complex of variable size (Fig. 2b, d, e, f, m). A trapped ophiolite (Fig. 2c, m), or continental basement, may form directly the inner wall of the trench (as in the case of the Arequipa Massif, Peru-Chile trench: Fig. 2g). This latter case may come about because of tectonic erosion or strike-slip removal of a preexisting inner wall consisting of an accretionary complex or an ophiolitic fore-arc basement. The accretionary complexes are made up of material scraped off the subducting slab including both sedimentary and igneous rocks of the ocean floor (the former usually dominating by far) and/or the turbidites filling the trench fed both across, from the arc and from the fore-trench bulge, and along, its axis. Accretion occurs where sediment thickness in trench exceeds 500 m to 1 km, whereas in places where that thickness is below 500 m subduction erosion takes place. The scraped off material is stacked into thrust slices commonly verging towards the trench, but in some (e.g., Washington State and Gulf of Alaska trench inner slopes) a landward vergence can also develop already in the trench inner wall, possibly resulting from the presence of low-strength, probably overpressured, zones in trench and slope sediments and the presence of oceanward-dipping surfaces of weakness in the trench fill. In some accretionary complexes, especially the large ones such as the Alaskan wedge, major vergences both synthetic and antithetic to subduction may develop. Deformation in accretionary complexes is penetrative leading to much dewatering, in places lubricating the decollement under the accretionary wedges (e.g., in the Seram Trench in Indonesia, in the Franciscan and Kodiak complexes in the North American Cordillera, and in the Ligurian units in the Appenines), and foliation development. In most large accretionary wedges, the wedge overthrusts the backstop, that is, the arc massif, along later-developed “secondary” thrusts. Accretionary wedges may be less than 2 km thick (e.g., in the Peru Trench: Fig. 2h) to some 36 km thick (e.g., in the Cascadia Accretionary Wedge). Where they are caught up in collision zones, they may further thicken to more than 70 km as in the Songpan Ganzi System in eastern Tibet (Fig. 2k). Metamorphism in them ranges from none at their surface to granulite grade along the bottoms of thick wedges where, along with much underplating, spreading centers have been subducted, as in the Chugach Mountains in Alaska. Where trench sedimentation is extremely limited as in intraoceanic arc systems such as the Marianas, the arc-trench gap may form from trapped oceanic lithosphere, essentially an ophiolite, because it is now incorporated into an orogenic edifice (Fig. 2c). In the Marianas, serpentinite mud volcanoes bring fragments of early Eocene blueschists formed at around 16 kb and 590 °C to the fore-arc surface indicating that such subduction systems do preserve products of their earliest history. Fore-arc magmatism occurs sporadically when spreading centers are subducted, as, for example, along the Aleutian and the Nankai trenches or where the fore-arc is

cracked by normal faulting perpendicular or subperpendicular to the arc axis, as between Mt. Hood and Portland, Oregon, in the Cascade arc in the northwestern United States. In extensional intraoceanic arcs, basalts to andesitic basalts to dacites, in places even rhyolites, although very sparse, are also observed in the Mariana, Izu-Bonin, and Tonga fore-arcs and these seem to be fed by the closest arc volcanoes along dykes and sills.

Above the fore-arc are usually located one or more fore-arc basins, such as the Great Valley in California, the Paita-Yunguilla Basin, and the older Celica-Lancones Basin in Ecuador, Pampa del Tamarugal in the Central Andes (Fig. 2g) or the Cretan Basin in the southern Aegean, the Andaman/Nicobar/Sunda fore-arc basins (Fig. 2f). Of the above examples the first group contains shortening, the second strike-slip and the third extensional basins. Such basins may in turn be of various subtypes, that is, shelved *vs.* sloped, terraced: ponded (filled *vs.* unfilled), imbricated; ridged: narrow, broad, and terrestrial upland types (Dickinson and Seeley 1979) depending on the predominant strain creating them, the topography and nature of the fore-arc region (continental *vs.* oceanic, or accretionary), the availability of sediment influx and climate. In the case of the intraoceanic ensimatic arcs, the fore-arc basement may consist entirely of oceanic lithosphere, commonly devoid of thick fore-arc basin fills (e.g., in the case of the Mariana fore-arc: Fig. 2c).

In many fore-arc systems, an upper slope discontinuity separates the fore-arc from the arc massif (Dickinson and Seeley 1979), forming the core of a subduction-controlled orogen. That discontinuity manifests itself as a break in slope determined by a fault that may be of any kind depending on the strain regime governing the evolution of the arc.

The arc massif and shortening retro-arc areas with flexural hinterland basins: In subduction-controlled orogens, the arc massif is the core of the orogen (Fig. 4a, b). It shows great variability in terms of rock composition, structure, and topography, ranging from (1) the dominantly mafic, extensional, low-lying island arcs, such as the Marianas (Fig. 2c), (2) through the deformationally neutral continental arcs of moderate topography characterized by dominantly andesitic volcanism, such as the Sumatran arc (Fig. 2f) (3) to the majestic mountains showing great across-orogen shortening, flanked by thrust belts and flexural basins on both sides, crowned by andesitic to rhyolitic volcanoes with subordinate basaltic volcanism and immense batholithic intrusions ranging from tonalitic through granodioritic to granitic compositions, such as the Andes (Fig. 2g, h). Within the arc cores, deformation is characterized by ductile deformation in levels where temperature exceeds about 580 to 600 °C and pressures reach and exceed 4 kb. Large, close to isoclinal folds (nappes of the first genre) dominate the structure at such levels (Fig. 4c), such as the Islay Anticline and the Tay Nappe formed from the Ardisaig Anticline in the Scottish Caledonides or the refolded isoclinal to

close fold nappes of the Thor-Odin Dome in the Canadian Cordillera. At higher structural levels, one sees typical fold-and-thrust belt geometries with little to no metamorphism, into which some intermediate to felsic plutons rise (e.g., in the Cordillera Huayhuash in Peru; in the Cariboo Mountains in the southern Canadian Cordillera). In the highest parts, in Altiplano-type high plateaux, brittle, nonpenetrative, germanotype structures take up orogen-parallel extension and orogen-normal shortening. Usually, the upper, less metamorphosed carapace is detached along thrusts and/or low-angle normal faults from the highly metamorphic core. In such orogens, large fold and thrust belts in the hinterland area are in turn flanked by wide flexural hinterland molasse basins of the type of the Llanos and Pampas of South America (Fig. 4a), or the vast Western Interior Basin behind the North American Rocky Mountains. The tectonic difference among the various types is dependent on whether the arc is extensional, neutral, or shortening. In all three types, arc-subparallel strike-slip faulting, both of arc-slicing and arc-shaving types, may be present depending on the angle of relative convergence of the subducting and the overlying plates. Especially the arc-shaving strike-slip faults give rise to significant coastwise transport of fore-arc material. Thus, not all fore-arcs have developed in front of the arc segments they now neighbor. Arc cores of especially Andean-type shortening orogens house not only high-grade metamorphic rocks, but also large, composite intrusions, such as the tonalitic/granodioritic/granitic Coast Mountains Batholith in Canada, Idaho, Sierra Nevada, and Peninsular Ranges batholiths in the US Cordillera, the immense Coastal Batholith of southernmost Ecuador and Peru, and the northern and southern Kuen-Lun plutons (e.g., Shahidulla) of felsic composition in northern Tibet, softening the orogenic edifice. This leads to underthrusting of the hinterland under the arc massif for considerable distances leading to the formation of the thin-skinned hinterland fold-and-thrust belts (Figs. 2g and 6a). This brings up the problem of the strain history in such orogenic cores: in the USA and Canadian Cordillera, it is widely believed that the core eventually collapsed under its own weight and created the extensional metamorphic core complexes (e.g., Armstrong 1982; Coney and Harms 1984). Yet, in the Andes, nowhere do we see any significant orogen perpendicular extension, despite the prodigious height of the orogen and a crustal thickness exceeding 75 km, especially in its central part. Moreover, Glombick et al. (2006) disputed the earlier interpretations of the Shuswap metamorphic complex: they wrote, “The shear zones, which yield upper plate to the west shear-sense indicators, are interpreted as the northern extension of the Okanagan Valley fault. Farther east, near the north-south axis of the complex, superstructure and infrastructure are separated by an attenuated metamorphic section, but evidence of noncoaxial strain is lacking. Discrete detachments were not found. Steeply dipping normal faults cut low-angle shear zones and do not merge with

them at depth. Middle Eocene volcanic and sedimentary rocks rest unconformably on metamorphic basement. The continuity of superstructure indicates that infrastructure was not exhumed by crustal-scale detachments.” (their p. 245). They propose that the late Cretaceous to early Tertiary partial melting of the middle crust resulted in the development of a zone of channel flow. As the channel was underthrust by a crustal-scale ramp in the underlying, more competent Palaeoproterozoic basement, it was exhumed from depths of 20–30 km and thinned vertically. Shear zones between infrastructure and superstructure are interpreted as being a transient rheological interface at the upper boundary of the channel, which in places may very well show a normal separation. Such an interpretation, also involving upper crustal stretching but without “gravitational collapse,” which seems very difficult without massive magmatic weakening of the crust, seems more compatible with world-wide observations. Where arc magmatism is feeble to nonexistent because of a very low angle of the subducting slab, shortening may disrupt the cratonic edge rimming the orogen in the hinterland area giving rise to large, thrust-bound, thick-skinned basement uplifts such as those in the US Rockies or the Sierras Pampeanas in northwest Argentina (Fig. 2h).

Back-arc: One or more extensional basins, which may or may not be floored by oceanic lithosphere, are located behind extensional arcs (Fig. 6c), such as those of the Sea of Japan, or the Parece Vela Basin and the Mariana Trough (Fig. 2c), or the Tyrrhenian Sea (Fig. 2d). Where oceanic, such back-arc, or marginal basins commonly have crusts thicker than normal oceanic crusts ranging from about 9 to 30 km. In continental back-arc basins, the crust may be thinned down to 6–8 km. Within the back-arc basins, volcanism is commonly, but not exclusively, tholeiitic basaltic and in places may be alkalic. Not all back arc basins are extensional. If a subduction zone develops far from a continent within an ocean, it may “trap” oceanic lithosphere behind the arc massif giving rise to a “marginal” basin. The Philippine and the Aleutian Basins are examples of such trapped marginal basins. In the case of such basins, the nature of the arc is immaterial for the formation of the basin.

Marginal basins do not often develop into major oceans, although examples of such development are well-known from the history of the Tethysides. Most seem to have life-spans of about 60 Ma and when starting to close back, fold and thrust belts may develop between the arc massif and the marginal basin behind it (e.g., as in the Sado and Okushiri Ridges along the western margin of Honshu and Hokkaido in the Japan Sea).

In case of neutral arcs, the epi-arc and hinterland areas have small basins commonly controlled by strike-slip tectonics parallel with the arc massif, such as the early Cainozoic coal and hydrocarbon basins behind the Sumatra arc axis, partly controlled by strike-slip-related secondary extension, especially in the North (Lho Sukon, Jawa, and Tamang deeps

bordering the Barisan mountain front) and Central (Balam, Kiri, Amon, Kampar Kanan, and Bengkalis grabens) basins.

Collision-Controlled Orogens

In collisional systems (Fig. 3c), the asymmetry of structure is dictated by the foregoing subduction. Collision begins when a nonsubductable continent, carried by the subducting plate, is fed into the subduction zone. In such a situation, the fore-arc is usually obliterated (e.g., along the Indus Suture south of Lhasa; partial preservation farther west near Xigatze). In other cases, major parts of the fore-arc may be preserved in the form of overriding ophiolitic and *mélange* nappes (e.g., along the Intra-Pontide suture in Turkey or along the Himalayan margin). More extreme preservation of a fore-arc may occur in case of an extended Atlantic- or Californian-type continental margin, on which a magmatic arc had not developed to any extent, overrides the incoming continent (as the Austroalpine units did in the Alps). The incoming continent may be a major cratonic piece with its peripheral continental margins such as

India, or it may be just an ensialic island arc, such as the Rhodope-Pontide Fragment in northern Turkey, or even a well-developed ensimatic arc, as in Oman. *In collisional orogens, the incoming, that is, the underthrusting, continent is always the foreland* (e.g., India in the case of the Himalaya; Central Europe in the case of the Alps; Arabia in the case of the Zagros; Eastern Europe in the case of the Urals; Siberian Craton in the case of the Verkhoyansk Mountains).

Collision-controlled orogens are at least as multifarious as the subduction-controlled ones, but their basic architecture is the same in all (Fig. 7). In Fig. 7a, two continents are approaching each other by eliminating the intervening ocean by subduction under continent II. Notice that no details are given of the structure to keep the figure as general as possible. Figure 7b shows the situation once the collision is accomplished. Here it is implied that the foregoing subduction vergence also determines the orogenic vergence initially. As orogeny evolves, a foredeep develops because of the isostatic loading of the incoming Continent I by the developing orogen

Orogenic Belts, Fig. 7 A highly simplified and schematic series of cross-sections (a–d) illustrating the basic stages in a continent-continent collision

as seen in Fig. 7c. Finally as the orogenic edifice rises, gravitational potential makes it more efficient to develop backthrusts, in front of which this time a backdeep develops (Fig. 7d). When well-developed Cordilleran orogens collide with other continents, their already well-developed backthrust/backdeep areas become inherited by the collisional orogen, as, for instance, in the Transhimalaya Range. Here a terminological muddle needs clarification: in most geological publications dealing with the American Cordillera, the vast backdeeps are almost universally referred to as “foredeeps” and the cratons bordering the Pacific-facing orogen as “foreland.” This led to the development of such absurd and inconsistent terminology as “retro foreland basin,” meaning “back front basin.” The confusion has deep roots going back to James Dwight Dana in the middle of the nineteenth century, who considered all orogens to face continents away from bordering oceans. This was rectified by Suess in 1885 who correctly recognized the Pacific Ocean floor as the foreland of the entire Cordillera, but later, in 1909, he too became confused and mentioned both Laurentia and Brasilia (Guiana+Amazonian+São Francisco+Rio Apa+Rio de la Plata cratons) as forelands as a result of the discovery of the extensive thrusting in the Subandean chains that led him to consider the Andes as a bilaterally symmetric chain. However, plate tectonic theory restored the asymmetric structure of the Cordillera by recognizing the Andean subduction as the main motor of the orogeny there. Clarifying this confusion is important, because in many publications with titles involving the word “foreland” hinterlands and hinterland basins are also (in places, exclusively!) described.

There are two main types of collision-controlled orogens: override and nonoverride types (Fig. 8). The “override” refers to overriding of one of the colliding continents above the other one for considerable distances at shallow structural levels (~ 15 km; Fig. 8a). This happens when the maximum width of the closed ocean was not sufficient to generate a well-developed continental margin magmatic arc upon subduction (about 400–600 km), as, for instance, in the case of the Alps. In that case, two thinned continental crustal pieces collide and the overlying plate easily thrusts above the underthrusting one for very considerable distances (Şengör 1991b). In the nonoverride types, none of the colliding continents override the other one at shallow structural levels, because the intervening ocean was wide and therefore its subductive removal generated a well-developed continental margin arc with a thick crust prohibiting it from mounting the incoming continent owing to excessive gravitational energy needed (Fig. 8b). Himalaya is the best-known example of such an orogen. When the subduction zone of the arc has accumulated an excessively large subduction-accretion complex, as in Makran or Alaska or Sikhote Alin today, its thickening upon collision with the incoming continent may stop continental convergence and the two continents may never come into

direct contact (Fig. 8c). The Kuen-Lun and the Altaids are examples of such “Turkic-type” orogens.

Despite the fairly simple outlines of orogenic architecture in both subduction- and collision-controlled orogens, the detailed structure of orogens on our globe is extremely varied depending on the nature of the interacting lithospheres and crusts (including their history), composition of the mantle underlying them, nature of the magmas that intrude them and extrude out of them, availability and nature of sediment, prevailing climate in where they develop, duration of their development, and the rate of plate interaction creating them. All these factors are in turn interdependent generating extremely complicated structures and evolutionary histories. In the next section, the various species of orogens are presented, the term *species* here taken in its original Latin meaning: “appearance, quality” with no genetic implications. However, the reader must bear in mind that species of orogens do not maintain their identity throughout their history, but, almost as a rule, evolve into each other. Therefore, the “species” presented below should only be taken as entities often existing only during a specific interval of the life of an orogen. Such metamorphoses might be compared with the metamorphoses of certain insects, but such a comparison would be misleading, because insects follow a predetermined, unchanging course (barring mutations) guided by genetics, whereas the evolution of orogens is entirely contingent on the factors listed above. Even within one species, orogens may display a great variety that are not uniform enough to be designated as “races.” They are varieties, but the number of varieties are as many as there are orogens in any one species. This may be compared to the variety seen in human beings. No two humans are identical, but they all have the same *Bauplan*. It is that *Bauplan* the species concept in tectonics unveils to us and enables us to employ a kind of “comparative anatomy of orogenic belts.”

Species of Orogens

Figure 9 illustrates a hierarchical classification of orogens. All orogens are products of convergent plate boundaries. Four types of convergence may create orogenic structures:

Transpressional orogens (Fig. 9i): For a transpressional structure to count as an orogen, it must involve subduction. Subductionless transpressional structures may be very major edifices, such as the Transverse Ranges in California or the Qinghai Nan Shan in northeastern Tibet (Fig. 2a), yet they are parts of the strike-slip regime, often parts of major keirogens, and not orogens.

Transpressional orogens may form along continental margins (Fig. 9A) or entirely within the ocean (Fig. 9B). Example for the former is the entire Sumatran subduction zone controlling a transpressional orogen above it that has given rise to strain partitioning by creating the Sumatran Fault. The Hikurangi Trench in the North Island of New Zealand carries

Orogenic Belts, Fig. 8 Styles of collisional orogens

TYPES OF COLLISIONAL OROGENIC BELTS

above it also a transpressional orogen with strain partitioning expressed by the Kekerengu Strike-Slip Fault. The Tonga-Kermadec subduction system, the northerly prolongation of the Hikurangi Trench, is also transpressional with strain partitioning creating a right-lateral strike-slip system within the arc and head-on subduction in the trench. The Aleutian subduction zone/magmatic arc system, connecting the Queen Charlotte Transform Fault and the Bering-Kresta Transform Fault, is partly a transpressional orogen, at least west of the Atka Island ($52^{\circ}08'17''$ N $174^{\circ}26'43''$ W). Similarly, the Florence Rise and the entire magmatic system behind it in Central Anatolia is a perfectly good transpressional orogen with a part

of the Eastern Mediterranean Ridge in front of it. The Macquarie transpressional system with increasing amounts of convergence to the south along the Hjort Trench is a purely intraoceanic example. Thus, transpressional orogens may be of various sorts depending on the type of crust involved, the degree of obliquity of the subduction along them, and, if present, the influence of the bounding strike-slip boundaries.

Subduction-controlled orogens (Fig. 9ii): subduction controlled orogens may be of various types depending on the nature of the interacting lithospheres. The simplest form is that of intraoceanic arcs formed by intraoceanic subduction zones (Fig. 9Ca). If the arc is extensional, a system of low-

Orogenic Belts, Fig. 9 A hierarchical classification of orogenic belts. I, II, and III are three end-member plate boundaries. Orogens originate only from convergent boundaries, that is, from III. (Modified from Şengör (1990a))

lying, dominantly mafic intraoceanic island arc (e.g., the Mariana arc) and various generations of marginal basins behind it (e.g., the Mariana Trough and the Parece Vela Basin; Fig. 2c) separated from one another by remnant arcs (e.g., West Mariana and Palau-Kyushu Ridges) constitute the orogen. The arc and the expanding youngest marginal basin are often the only active parts of the orogenic system.

The continental margin arcs are the most prominent subduction-controlled orogen species (Fig. 9Cb, Dd, Ef). The extensional varieties (Fig. 9Cb) create ensialic arcs torn from continents or from other ensialic arcs opening back-arc basins behind them. The Japanese islands with the Japan Sea marginal basin behind them are the best-studied examples of ensialic arcs torn from a continent. Arcs torn from continental arcs are best represented by the Inner Apennine massifs torn from Sardinia/Corsica, which in turn had been torn from continental Europe in Iberia opening behind them the Tyrrhenian and the Algero-Provençal Basins respectively (Fig. 2d).

If the arc is neutral (Fig. 9D), no marginal basin develops (unless one is trapped). An intraoceanic example (Fig. 9Dc) is the Central Aleutian island arc system between the islands of Unalaska and Atka (a length of about 500 km; the Aleutian Basin oceanic lithosphere behind it is a trapped piece of the Pacific Ocean floor). For neutral continental margin arcs (Fig. 9Dd), the Makran in Pakistan and Iran (Fig. 2e) is possibly the best continental example with the majestic arc volcanoes of Kuh-e Bazman, Kuh-e Taftan, and Kuh-e Sultan.

Shortening arcs (Fig. 9E) in intraoceanic settings (Fig. 9Ee) almost always results in subduction polarity flipping, as, for example, happened in the Vitiaz/New Hebrides Trench systems in the Southwest Pacific Ocean. Shortening intraoceanic arcs almost always come into being when a buoyant oceanic object, such as a seamount chain or an oceanic plateau, reaches the trench associated with the arc and makes subduction difficult. In the case of the Vitiaz

Trench, it was the arrival of the Samoan island chain of oceanic volcanoes that choked the trench and led to arc-perpendicular shortening. Shortening of continental margin arcs (Fig. 9Ef) commonly create majestic cordilleran chains with doubly vergent deformation on both sides of the arc massif housing large plutons such as those of North, Central, and South America (Fig. 2g, h) and the Sikhote-Alin Orogen in Northeast China and the Russian Far East.

Collision-controlled orogens (iii, iv): There are two fundamental types of collision-controlled orogens as mentioned above. The continental override types result from the collision of arcs or two major continents across the closure of small oceans of the Alpine type (Figs. 8a and 9ivF). The closure of the Antalya Ocean in southern Turkey is an example of the first (e.g., Okay and Özgül 1984) and the closure of the Alpine Tethys (e.g., Pfiffner 2014) is the example of the second one. Inevitably the arcs associated with such orogens are either very poorly-developed, as in the Alps, or not developed at all, reducing the orogeny to the collision of a small continental sliver with another arc. In fact, all Alpidic orogens west of the Carpathians belong to one or the other of the override type collisional orogens (Wildi 1983; Pfiffner 2014). All major ophiolite obductions actually belong to this category (Figs. 2i and 9iiiC), because almost all represent collision with a continental margin of an ensimatic arc or a piece of oceanic lithosphere generated above a subduction zone by prearc spreading (Şengör 1990a).

The noncontinental override type orogenic belts are basically of three kinds (Fig. 8b, c): arc-arc collisions (Fig. 9Gi) of the kind seen in Japan where the Izu-Bonin arc is ramming the Honsu arc and creating the syntaxis of the Fossa Magna, arc-continent collisions (Fig. 9Gj), and continent-continent collisions (Fig. 9Gl). However, notice that all island arc-island arc collisions must be in reality the collision of two subduction-controlled orogens and should not be considered under fundamental orogenic types. Similarly, the collision of an island arc with a continental margin arc, facing each other (Figs. 2m, n and 9Hn) or facing in the same direction (Fig. 9Gk), similar to the collision of the Panama Arc with the northern Andes also represents the collision of two orogens and should similarly fall out of the list of the fundamental types of orogens. By contrast the collision of an island arc with an Atlantic- or California-type continental margin creates a single, continent-facing orogen (Fig. 9Gj). An island-arc facing away from a nearby continent would not be able to generate a collisional orogen, because the arc would not be able to approach the continent. Ensialic arc-continent collisions with an arc facing the continent are well-known: in northern New Guinea, in Kamchatka, in western Turkey, west of Ankara (Fig. 2l), in Southeast Asia, in Taiwan and the Luzon Arc in the northern Philippines. As pointed out above, all supra-subduction zone ophiolite obduction events and the ensuing orogenic belts result

from ensimatic arc-continent collisions; more developed ensimatic arcs that collided with Atlantic-type continental margins are also known, for example, the Kohistan Arc in the western Himalaya. In arc-continent collisions, there are cases where the geological evolution makes the slotting of an orogen into a category impossible: in the southern Andes, the northern end of the Rocas Verdes Basin closed without any subduction, but by squashing and folding the Sarmiento ophiolite without much of a dominant vergence. In this case would one consider the structure as an orogen resulting from an arc-continent collision, or simply a continental margin arc orogen? Towards the south, the Rocas Verdes Basin became wider and here an arc-continent collision is more obvious with a clear northerly vergence of the Tortuga ophiolite and that is why the closure of the Rocas Verdes Basin is considered an orogenic event by itself. However, the problem becomes much more acute in case of even narrower intra-arc basins floored by oceanic lithosphere, such as those behind the New Hebrides arc. Subduction in such a case is essentially impossible and, consequently, the closure of such basins must be considered as an intra-arc event and not an independent orogeny.

Orogenic Collages

The major mountain belts of our globe, even the youngest and still active ones, rarely consist of a single orogen. For example, the Caledonian/Appalachian System has many orogens of diverse types within it and the end result is what James Helwig in 1974 called an “orogenic collage.” The reason that the correct recognition of the constituents of orogenic collages is important is to be able to dissect the orogenic complex formed from them correctly and thus reconstruct its evolution accurately. Failure to do this would result in subdividing an orogenic edifice on the basis of inappropriate criteria resulting in the proliferation of nameless “tectonic units” that serve no purpose in understanding geological processes and the history of orogenic complexes. The rise of “terranoology” in the North American Cordillera is one example of such a sterile methodology (see Şengör 1990b). Fig. 2m, n illustrates further examples of “symmetric orogenic complexes” formed from more than one orogen, but often, erroneously, called “an orogen” (e.g., the Caledonian “Orogen” or the Appalachian “Orogen”).

Magmatism in Orogens

Magmatism in orogens occurs in two main settings: subduction magmatism and collision magmatism. Although fore- and hinterland magmatism may be caused by orogeny (e.g., the rifting-related magmatism of the Upper Rhine Rift being caused by the Alpine collision to the south), it is not considered a part of the orogenic phenomena.

Subduction Magmatism

Subduction magmatism shows a very great variety on the basis mainly of the nature of the arc (extensional, neutral, or shortening, with an ensimatic or ensialic arc massif), subduction dip angle, and the nature and amount of the sediment being dragged into the subduction zone which are functions both of the nature, and the amount of sedimentary fill, of the trench and the prevailing climate.

Subduction magmatism is generated by the release of volatiles (mainly water and CO₂) from subducting slabs and their percolation upwards in the mantle wedge above. Subduction generates a pressure minimum at the apex of the wedge where much of the generated high-Mg mafic magma resulting from 2 to 8% melting is gathered. From here the magma escapes directly upward, most likely by creating its own fractures and not along the so-called “megathrust” of the subduction zone because of the low temperature there. This magma creates the magmatic arc axis and the magmatic front. “Hydrous phases in the subducted slab decompose at levels shallower than 100 km, that is, beneath the fore-arc region. The slab-derived H₂O, enriched in incompatible elements with larger ionic radii, reacts with the overlying mantle wedge materials to form polluted amphibole peridotite. The polluted peridotite is transported downward on the slab. . . . Amphibole in the dragged peridotite decomposes at a depth of about 110 km, just beneath the volcanic front. H₂O released migrates upward to reform amphibole peridotite in the higher-temperature and lower-pressure region. When the front of amphibolization reaches a level at which the solidus temperature of amphibole peridotite is distributed, initial magmas are produced and rise as a form of mantle diapir.” (Tatsumi 1986, p. 717). The interesting thing is that the base of the oceanic lithosphere, commonly at about 100 km, coincides with the peridotite solidus. Thus, there seems to exist a double control of the position of the magmatic front in subduction-controlled orogens. Rise of magmas from initial partial melting to the surface takes about 30 Ma (Turner et al. 2004). The magmatic front has been used as a *file-d’Ariane* to reconstruct now disrupted subduction-controlled orogens (Şengör et al. 1993). The 30 Ma gap mentioned above shows that when magmatic fronts are used for reconstruction purposes, time intervals >30 Ma must be considered (ideally 50–60 Ma).

Sediments coming into the subduction zone are in part dragged down into the magma generation zone, but not much beyond. In sediment starved subduction zones, the generated magmas are mainly basaltic, being island arc tholeiites with subordinate dacites and even rhyolites resulting from local differentiation. As arc magmatism matures, more and more calc-alkalic magmas begin replacing tholeiitic magmatism. In continental margin arcs andesites dominate where the arc is neutral and andesites and rhyolites dominate where the arc is actively shortening. In Sumatra, for example, where the arc is neutral, magmatism begins with andesites and

basalts with subordinate felsic rocks, goes through a phase of explosive volcanism with andesites and rhyolites, and then returns to an andesitic basaltic phase. During the Plio-Pleistocene, basaltic effusions cease almost entirely and the arc magmatism is dominated by andesites and rhyolites with rare basalts.

Where the arc is actively shortening felsic magmatism dominates together with andesites, as in the Andes, Central and North American Cordilleras; in the Transhimalayan Arc before the Himalayan collision; in the Lachlan Orogenic Belt in eastern Australia. In the hinterland parts of the magmatic arcs in shortening orogens, continental crustal melting becomes significant and tin mineralization is widespread. Some of the Na-rich trondjemite/tonalite/ignimbrite magmatism in the Andes of Peru may result from the partial melting of underplated basaltic lower crust and probably did not come either from the subducted slab or from the mantle wedge. The generation of trondjemite/tonalite complexes during the Mio-Pliocene has important implications for the origin of their Archaean analogues. Low-angle subduction may lead to slab melting and adakitic arc magmatism, as for example, in the Yanshan Belt of north China, where it occurs alongside basement-involved shortening.

The morphology of volcanoes is controlled by the composition of their products and represents an important factor in governing the topography of the magmatic arc and the resulting efficiency of subaerial erosion and concomitant sedimentation. The table (e.g., Columbia River Flood Basalt Province) and shield (Marianas) volcanoes have very subdued relief, with few of the volcanoes rising above sea-level as in the case of the Marianas or the Tonga-Kermadec arc. In such arcs, sediment production is slow and consequently the trenches remain empty and accretionary complexes grow very slowly or not at all. By contrast, where volcanoes are andesitic, steep-sided stratovolcanoes dominate the arc creating a sharp, but regular relief with much erosion and sedimentation. The associated trenches are usually full and give rise to substantial subduction-accretion complexes as seen in Japan, Sumatra, in eastern Alaska, the Cascade subduction zone in the northwestern USA, Central America or in Makran. In shortening arcs, crustal shortening is mainly responsible for the generation of high ground, but there also, the stratovolcanoes and rhyolite domes and ignimbritic blankets contribute to the creation of the rough and jagged topography that facilitates erosion of the high-standing edifices and the transportation of the produced sediment. It is to be remembered that the highest point above the Earth’s center is not Mt. Everest, but the summit of Mount Chimborazo in Ecuador, an Andean stratovolcano located one degree south of the Equator, where the Earth’s rotational bulge is greatest.

Magmatism in extended back-arc basins is basaltic, generally with significant subduction contribution, but may be even alkalic as in the case of the Utsuryoto Island in

southwestern Japan Sea. The thickness of the oceanic crust in them is more variable than that in the major oceans, reaching in places thicknesses of 30 km, not dissimilar to oceanic plateaux (Bransfield Strait: 30 km; Algero-Provençal Basin: >20 km; Yamato Basin of the Japan Sea: 14–16 km; Japan Basin of the Japan Sea; Banda Sea: 9–10 km) but in others showing normal oceanic thicknesses (e.g., Shikoku Basin: 5–7 km; Kuril Basin: 5–7 km; Tyrrhenian Basin: 6 to 8 km); yet others displaying significant variation between 5.5 and 9 km within the same structure as in the Lau Basin and from 20 to 28 km in the Black Sea basins. Not all back arc basin floors are homogeneously oceanic: the Japan Sea, for example, is underlain mostly by continental crustal patches of various thickness and only a triangular area between northernmost Honshu, Hokkaido, and southernmost Sikhote Alin is truly oceanic. The same thing is true for the Black Sea where the Arkhangelsky and the Andrusov ridges, forming the Mid-Black Sea Ridge, separate the two oceanic halves of the basin. This has important implications in interpreting the geology of the now-closed back-arc basins encountered in orogenic belts. For example, an extreme case is illustrated by the evolution of the Tasman Sea, which is the best analogue for the Mesozoic/Cainozoic evolution of the Mediterranean Apides in Turkey and surrounding regions.

Collision Magmatism

Magmatism does not cease in an orogenic belt after continental collision, but lasts until all orogenic activity comes to a close. Along collision belts two types of collisional magmatism dominate: (1) Slab break-off magmatism and (2) crustal thickening magmatism. In addition to these, the formation of important strike-slip related extensional basins within collisional orogens may localize basaltic volcanism in places accompanied by shallow crustal melts (as, for example, in the Erzincan pull-apart basin along the North Anatolian Fault in Turkey) and so can crustal fissuring at high angles to the orogenic convergence direction (e.g., the Nemrud Volcano in eastern Turkey). The most spectacular present-day example of a slab break-off magmatism is seen in the actively shortening Turkish-Iranian High Plateau. Over half of the Turkish-Iranian High Plateau is covered with collision-related young volcanic rocks (~43,000 km²), ranging in age from 11.4 Ma to the seventeenth century. Although it is difficult to calculate the total volume of the volcanic material produced because of variations in the thickness of the volcanic succession and erosion in the region, the estimated total volume is a minimum of 15,000 km³. The erupted volume may, however, represent only a small fraction of the melt generated beneath the region, because a greater proportion presumably was emplaced deeper in the crust in the form of plutons. Although fissure eruptions dominated the volcanic activity (with some N-S fissures as in the case of Nemrud), there are over 20 major volcanic centers and numerous smaller ones on the plateau,

corresponding to central eruption sites. The volcanic rocks of the plateau span, remarkably, the whole compositional range from basalts to rhyolites. There is, however, a significant north-south variation in lava chemistry between the north and the south parts of the plateau. The volcanic units of the northern areas are calc-alkalic, whereas those of the south are mildly alkalic to alkalic in character (even phonolites are known). Slab break-off-related magmatic massifs, housing large porphyry copper/gold deposits, with attendant tectonism has been studied in detail in New Guinea. The magmatic rocks are mostly intermediate in composition resembling arc rocks in their major element content, but also contain those giving “intraplate” signatures. There are also basalts and lamproites. Where this magmatism is west of the Tasman Line, it involves signatures of the Precambrian crust, to the west, it only has younger influences as expected from the composition of the crust through which they erupted. The mainly felsic Eocene magmatic rocks in northwestern Turkey were similarly results of a slab break-off following the closure of the İzmir-Ankara suture south of the Sakarya continent.

In Himalaya and Tibet, the collisional magmatism appears to be related to the thickening of the crust, much in the way originally suggested by Dewey and Burke (1973). In the Himalaya, the “suture-crossing” collisional magmatic rocks are represented by true leucogranites, the younger members of which (27 to 16 Ma “hair granites”) have facilitated the extensional collapse of the mountain front (Burchfiel et al. 1992). Whether the loss of the mantle lithosphere under Tibet actually happened is still controversial from the viewpoint of the available seismic data and thus difficult to consider in its rôle in generating magmas under the high plateau. However, the Oligocene to Recent vulcanicity on the Plateau north of the Indus-Yarlung suture began with highly undersaturated lavas in Central Tibet in the Oligocene. Typical calc-alkalic volcanism was active in the southern part of the plateau during the Miocene and highly incompatible element enriched ultrapotassic vulcanicity has characterized the Pliocene to recent activity in northwestern Tibet. This is not thought to be compatible with a wholesale underthrusting of the Indian craton under Tibet. The “suture-crossing” post-collisional tin-bearing granites of Cornwall, which extend westward into the Isles of Scilly and the submarine outcrop of Haig Fras, are considered similar in origin to the Himalayan granites, in that they too occur as multiple intrusive sheets into nappes on the foreland side of the Hercynian suture. High-K calc-alkalic postcollisional granites are also known from the Neoproterozoic Pan-African orogenic system, where in places they are associated with extensive strike-slip faulting, much like in northern Tibet today.

Rift-related alkalic and carbonatitic magmatism that in places accompanies the opening of oceans the closure of which gives rise to orogeny is usually not considered a part of orogenic magmatism, except in one case. Burke et al.

(2003) noticed that 90% of nepheline syenite gneisses and deformed carbonatites occur along Proterozoic suture zones in ancient collisional orogens. They infer from this observation that deformed alkalic rocks and carbonatites (DARCs) mark the places where vanished oceans have opened and then closed. They further infer that DARCs subducted down to ~100 km depths during collisions, as indicated by diamond-grade ultra-high pressure metamorphism in some collisional orogens, could provide source material for later alkalic magmatism and that this could account for the observation of recurrent alkalic magmatic activity over hundreds of million years in old orogenic provinces.

Metamorphism in Orogens

Metamorphism in orogens is related to magmatic events in arc cores and to tectonic burial in both magmatic arcs and collisional orogenic belts (Fig. 6). Holland and Lambert (1969) presented a synthesis of structural regimes corresponding to a given metamorphic grade. Their first regime is that seen below the level of diagenesis to the depth where metamorphic reactions begin. Here creep has a logarithmic relation to time, but other factors such as fluid pressure greatly influence the actual strains generated. The second regime is that between the onset of metamorphism and the first appearance of the epidote-amphibolite facies, where similar folds accompanied by schistosity and recumbent folds on all scales form. The third regime is that accompanying the epidote-amphibolite and amphibolite facies, in which deformation occurs by grain boundary or intralattice diffusion following the β creep law ($\epsilon = \beta t^n$; $n < 1$). Regime four is where a higher pressure amphibolite facies dominates and is characterized by partial melting, formation of gneissose structure, extensive flow folding, and possible onset of diapirism. The final regime is that of the granulites where laminar flow seems to dominate. The Holland and Lambert classes naturally apply to both subduction and collision metamorphism. Folding and thrusting under metamorphic conditions also fold and repeat the isotherms resulting in very complex metamorphic rock/structure relationships such as “inverted metamorphism.”

Below orogenic metamorphism is considered under the two headings of subduction- and collision-related metamorphism.

Subduction-Related Metamorphism

Before the advent of the theory of plate tectonics, Miyashiro (1961) pointed out that in active orogens around the Pacific Ocean a metamorphic belt of the andalusite/sillimanite and/or low-pressure intermediate type lies always next to the one characterized by jadeite-glaucophane and/or high-pressure intermediate type and the latter is always found closer to the ocean. In 1973, Miyashiro pointed out that the high-pressure

member of the pair is probably formed below a trench and the low-pressure member formed beneath a volcanic chain in the adjacent island arc or continental magmatic arc. He further observed that the low and intermediate pressure belt is associated with granitic/andesitic/rhyolitic magmatism, whereas the high-pressure belt is usually accompanied by tectonic slices of mafic and ultramafic rocks.

Our understanding of subduction-related metamorphism has not changed in principle since Miyashiro's perspicacious papers. Figure 6 shows the highly schematized isotherms in arcs and the corresponding mineral facies. The corresponding pressures may be obtained by looking up the metamorphic facies expressed by the index minerals and rocks in the figure. Figure 6a illustrates a shortening magmatic arc orogen. The normal geothermal gradients there (Fig. 6a) are disturbed both by the adiabatically rising plutons and the insertion of the cold oceanic lithosphere into the trench on the ocean, that is, foreland side and the insertion of the cold continental lithosphere in the hinterland. The insertion of the continental lithosphere on the hinterland side greatly augments the crustal thickness in the orogenic core and introduces into it radioactive minerals that generate heat.

Figure 6b is the situation of the isotherms in a neutral magmatic arc orogen and the corresponding rock-types. The difference between the neutral and the shortening arc orogens is that the former has no contribution of extra heat from the hinterland and, consequently, its magmatic activity is less vigorous. Figure 6c shows the situation in an intraoceanic arc where there is no preexisting continental crust and the only source of substantial heat comes from the magmatic activity of the arc and a slightly higher geothermal gradient commensurate with that of the oceanic crust. This higher geothermal gradient is offset by the introduction of the cold subducted slab into the subduction zone beneath the arc. Consequently, the intraoceanic arcs have the most subdued metamorphic zonation of all the arc types. The arc metamorphism is episodic in many arc terrains, which is a consequence of the episodic melt segregation and intrusion of plutons and the temperature sensitive rheology of the upper crust controlling the strength of the lithosphere.

Because subduction introduces cold material to very considerable depths (in places in excess of 100 km), a high pressure-low temperature metamorphism, also called “blueschist metamorphism” since the appellation used by E. H. Bailey in 1964 for the glaucophane schists in California, develops. Beyond about 39 km-depth coesite forms and near 100 km and beyond diamond crystallizes in deeply subducted rocks. The ultra-high pressure rocks are no longer low temperature-high pressure rocks, because their formation occurs near 17–20 kb and between 600 and 850 °C; they are simply “very high grade.” A particularly thorny problem has been to understand how such very deeply buried rocks return to the surface.

Collision-Related Metamorphism

Collision-related metamorphism is basically burial metamorphism, essentially Barrovian. This burial occurs by crustal thickening, most commonly by thrusting at the upper crustal levels and bulk shortening by folding and foliation development and even rock flowage in deeper levels as explained by Holland and Lambert (1969). Figure 10 shows its basic principles. In Fig. 10a two continents collide, whereby Continent I forms the foreland. The arrows in Fig. 10b indicate how the rocks in the descending continent will heat up as they are depressed below the normal continental isotherms, whereby heating is assumed to be instantaneous for graphic simplicity. In Fig. 10b, the orogenic welt rises isostatically bringing with it the heated, that is, metamorphosed rocks. The situation depicted in Fig. 10b is an idealized one, before any backthrusting begins. In reality, backthrusting would begin during the isostatic rise, or even earlier, as in the Alps, for example. Figure 10c depicts the situation after the advent of backthrusting and the development of an orogenic root. This would further raise the orogenic welt and the bottom of the root may begin partially melting creating the postcollisional granites such as those of Bergell and Novate in the Alps. As the orogenic welt rises, it gets denuded both tectonically and by attrition through the exogenic agencies and the updomed metamorphic isograds successively expose the mostly low pressure high temperature metamorphic facies within the core of the orogen, as, for example, is well-known in the Alps, where metamorphic rocks from prehnite-pumpellyite facies in the marginal thrust belts (Helvetic/Dauphine units in the external zones and the Southern Alps in the internalmost zones) are present as well as the granulite facies rocks within the orogenic core (e.g., the Ivrea Zone). The scenario shown in Fig. 10 is naturally overly simplified as it assumes a two-dimensional evolution where transition from one state to the other is instantaneous and the deformation is entirely brittle. In reality, convergence across a collisional orogen is rarely purely orthogonal to the collision front, the rate at which both the shortening proceeds and the rocks deform are very variable ranging from essentially zero in the western Alps to some 2 mm/a in the eastern Alps to 6 cm/a in the Himalaya and the structures range from highly ductile flow folds (where temperatures are about 600 °C or higher) to brittle structures as outlined by Holland and Lambert (1969). For example, in many collisional orogens, large-scale thrusting inverts the metamorphic isograds, as for example in the Himalaya or diapirism very much steepens, even overturns them and the loss of the lithospheric mantle beneath an orogen or the rise of a pluton may in places create even Buchan-type metamorphism (e.g., during the Grampian collision in the Scottish Caledonides or in the south Portuguese Hercynides).

In some orogenic belts, the foreland continent is dragged down to the subduction zone to depths of about 100 km to

create ultra-high pressure metamorphism, but it is important to realize that this metamorphism is *not* a product of the collision, but of the subduction that happens to outlive for a certain time the collision.

Geomorphology of Orogenic Belts

The sculpting of mountain belts is a complex process governed by internal processes that generally tend to increase topographic differentiation (except normal-fault-governed tectonic denudation decreases it) and external processes that diminish relief. For many years, it was believed that mountain erosion was very rapid and that mountains would disappear in a few million years, if not repeatedly elevated by ongoing internal processes. In the latter half of the twentieth century, it was realized that the denudation of a mountain range by attrition resulting from atmospheric and hydrological processes was critically dependent on isostasy and sea-level. Pitman and Golovchenko (1991) studied quantitatively the morphological evolution of mountain belts in the light of large (>200 m), long-period (>50 ma) sea-level changes. Based on the available data, they assumed that the rate of denudation of such old landscapes is proportional to the average regional elevation by a constant ($K \approx 10^{-4}/1000$ years). Thus, if the sea-level is approximately stable, it will take more than 300 m.y. and more likely more than 450 m.y. to degrade a Himalayan size mountain belt to a peneplain (in its original Davisian sense). For an old mountain belt that has been eroded to an average elevation of 500 m, it will take an additional 220 m.y. and more likely 390 m.y. to reduce to a peneplain. In a system in which the river valleys are graded with respect to base level, the rate of downcutting is enhanced by the rate of uplift caused by the isostatic response to regional denudation. With rising base level, the rate of valley incision decreases by the rate of rise. However, transgression of the river valleys cannot take place until the rate of river valley uplift caused by isostatic response to the denudation becomes equal to the rate of sea level rise. Under usual, that is, nonglacial, conditions of sea level rise, this will not occur until the landscape has been degraded to an average elevation of 60 m or less. However, under these conditions the decrease in the rate of downcutting in the river valleys greatly enhances the rate of degradation. As a consequence, older mountain belts already eroded to a regional elevation of 500 m or less may be further reduced to a peneplain during an episode of persistent sea level rise at rates of several tenths of a centimeter per 1000 years for several tens of millions of years. With sea level falling, the landscapes evolve toward an equilibrium surface at which point the rate of degradation is equal to the rate of sea level fall. Under such conditions, peneplains cannot form. The

Orogenic Belts,

Fig. 10 Evolution of metamorphism and collisional magmatism in an asymmetric collisional orogen

conditions for a steady-state of an orogen are difficult to realize because of the mobility of the interacting agencies such as the changes in the base level. Faulting is probably the dominant internal process that determines the geomorphology of the mountain ranges.

Economic Deposits in Orogenic Belts

Hydrocarbons

Hydrocarbons in orogenic belts occur in some fore-arc (e.g., in the Great Valley Forearc Basin in California) and hinterland

basins (e.g., in the Alberta Basin in the Canadian Rockies) in subduction-controlled orogens and in the fore- and hinterland-basins of the collisional orogens. In fact, the earliest uses of petroleum are known from three foreland basins (Zagros foreland: third millennium; BCE Sichuan Basin in China, which is also a hinterland basin with respect to the Tibetan Alpides, fourth century CE; 1859: Appalachian foreland basin in Pennsylvania). Some pull-apart basins within the orogen in places produce hydrocarbons (e.g., the Vienna Basin). Although some intramontane ramp-valley basins, such as those in eastern Turkey, have reported petroleum potential, no economic deposits have yet been discovered in them. The fore- and hinterland deformation areas of both subduction-controlled and collision-controlled orogens generate germanotype basins that contain important petroleum reserves (e.g., the Denver Basin in the US Rockies; Karamay Field in the Junggar Basin in NW China).

Coal

Coal mainly occurs in the fore- and hinterland basins of orogenic belts; but, if such deposits are later involved in a younger orogeny, some anthracite deposits may be encountered within the orogen itself (e.g., the ancient Heraclea coal basin in Zonguldak, NW Turkey).

Metals

It has long been known that almost all metals occur in orogenic belts, because they sweep together so many different environments and expose so many levels within the crust and upper mantle.

Building Materials

The world's most beautiful and famous, decorative building stones are obtained from orogenic belts, commonly from their metamorphic cores. All rocks from orogens in one way or another contribute to the building stone industry in the whole world, even the molasse basins (in fact, the word "molasse" is a Swiss stonemason's term).

Summary

An orogenic belt is a lithospheric structure that is formed by the collective work of any group of convergent plate margin processes.

Orogenic belts are major features of the lithosphere on which 98% of the world's largest earthquakes occur. Since the diameter of the Earth does not change to any appreciable degree, ocean-floor spreading and subduction must balance each other. Thus, the rate of deformation along orogenic belts must be almost 1.5 times higher than along the spreading centers, which is corroborated by the concentration of the largest earthquakes along them making them the most active

parts of the lithosphere. Orogenic belts are the main factories of the continental crust, at least since after the Hadean. Orogens house the world's main mineral wealth and an understanding of their nature is critical for successful mineral exploration. The basins flanking them and genetically associated with them contain a significant portion of the world's hydrocarbon resources. Knowing how they evolve is an indispensable part of oil and gas exploration on this planet. Finally, orogenic belts create mountains which control a good portion of the world's climate and climate in turn influences the growth of mountain belts.

Paleomagnetic Field Intensity

Andrew Biggin¹, Greig A. Paterson¹, Neil Suttie² and John Shaw¹

¹Geomagnetism Lab, Department of Earth, Ocean and Ecological Sciences, University of Liverpool, Liverpool, UK

²School of Archaeological and Forensic Sciences, University of Bradford, Bradford, UK

Synonyms

Archaeointensity; Palaeointensity

Definition

The strength of the ancient geomagnetic field and its variability through time can be deduced from various different types of measurements. *Absolute palaeointensities* are calibrated using a known laboratory magnetic field and can be recovered from any rocks retaining a thermoremanent magnetization yielding a palaeomagnetic measurement of the geomagnetic field intensity recorded at the time and place that the rock cooled down from above the Curie temperature of the magnetic grains. Similarly, *archaeointensity* measurements are made from heated archaeological artifacts (e.g., fired pottery). By contrast, *relative palaeointensities* provide uncalibrated records of geomagnetic intensity variations measured from the natural remanent magnetization of sediments, and *cosmogenic isotope palaeointensities* achieve the same using concentrations of cosmogenic isotopes as a proxy.

Introduction

Direct measurements of the intensity of the geomagnetic field only became possible in 1832 when a method of obtaining them

was developed by Carl Frederich Gauss (Stern 2002). If we wish to know how the field intensity has varied before this time, then we are required to use the geological and archaeological records to make indirect measurements. Palaeomagnetic approaches are based on the principle that, for weak fields such as Earth's, the intensity (M_{anc}) of the natural remanent magnetization (NRM) recorded by a material is linearly proportional to the strength (H_{anc}) of the palaeofield. For absolute palaeointensity measurements, the material in question must (except in very rare cases; e.g., Games 1980) have acquired a thermoremanent magnetization (TRM) whereas for relative palaeointensity, it is required to be a depositional remanent magnetization (DRM). Unfortunately, in both cases, the constant of proportionality linking the NRM to the palaeofield intensity is a sensitive and complicated function of the magnetic properties of the recording material and extremely difficult to measure directly. Absolute palaeointensity experiments obviate this difficulty by imparting the specimen with a new TRM (M_{lab}) in the lab by heating the specimen up and cooling it in a controlled field of known intensity (H_{lab}). The linearity relationships of the two types of M and H can then be combined to eliminate the constant and solve for the ancient field intensity:

$$H_{anc} = \frac{M_{anc}}{M_{lab}} H_{lab} \quad (1)$$

Depositional-type remanences cannot be reproduced reliably in the laboratory and therefore palaeointensity experiments performed on sediments produce records only of relative variations in H_{anc} .

In order for any type of palaeointensity measurement to be useful, an independent estimate for the age of the magnetization (often assumed or demonstrated to be the same age as the material) is usually required.

The first attempts to measure the ancient field intensity were made by Folgheraiter (1899) using archaeological vases, but with no reported success. Later, Koenigsberger (1936, 1938) and then Thellier (1941) made more serious attempts to recover past geomagnetic field strengths using igneous

rocks, baked archaeological materials and a sedimentary contact rock, respectively. It was somewhat later that the idea of Koenigsberger (1936) to obtain palaeointensity measurements from much older igneous rocks by comparing their natural thermoremanence to a laboratory-imparted field was properly tested (Wilson 1961). Absolute palaeointensity measurements from igneous rocks of all ages began in earnest in the mid- to late-1960s (e.g., Briden 1966; Coe 1967), and the discipline has been subject to numerous attempts to improve the methodology since (Table 1). Palaeointensity

measurements of all types are typically curiosity-driven, although the desire to understand geomagnetic polarity reversal transitions and geodynamo behavior more generally has provided a clear focus for some studies (Valet 2003).

Absolute Palaeointensity Measurements

Absolute palaeointensity experiments may only be performed using materials that have cooled from elevated temperatures

Paleomagnetic Field Intensity, Table 1 Selection of absolute palaeointensity methods currently in use

Family	Variants	Benefits	Criticisms
Thellier (Thellier and Thellier 1959)	Coe (1967); Aitken-Walton (Aitken et al. 1988; Walton et al. 1979); Perpendicular (Kono and Ueno 1977); IZZI (Tauxe and Staudigel 2004)	Sound theoretical basis for single domain grains; potential to recover estimate from a sample that contains both secondary magnetizations at low temperatures and that alters at high temperatures; additional checks for alteration (Prévot et al. 1981) and multidomain behavior (Krasa et al. 2003; Riisager et al. 2001) can easily be added	Multiple heatings are time-consuming and increase likelihood of sample alteration; bias due to multidomain effects may be prevalent in lava samples (Biggin 2010)
Microwave (Hill and Shaw 2000; Shaw et al. 1996)	All Thellier-type variants may be used	In principle, all benefits of Thellier, but with reduced sample heating in terms of both temperature and time; faster experiments that can be individually tailored to samples	Requires highly specialist equipment (microwave palaeointensity system); theoretical basis not yet firmly established; TRMs may not thermally unblock as sharply and as completely in microwave as in thermal experiments
Shaw (1974)	ARM-alteration corrections (Kono 1978; Rolph and Shaw 1985); Double heating (Tsunakawa and Shaw 1994); low temperature demagnetization (Yamamoto et al. 2003)	Original method is fast; arguably domain-state independent as uses full TRMs	The use of ARMs to check and correct for alteration in terms of the TRM properties is not always valid (Tanaka and Komuro 2009)
Continuous high temperature measurement	Wilson (1961); Le Goff and Gallet (2004)	Very fast methods; Wilson method is arguably domain-state independent as it uses full TRMs; Le Goff–Gallet method incorporates cooling rate and anisotropy corrections	Requires specialist equipment (high temperature magnetometer); samples must survive heating to Curie temperature without altering in Wilson method; unknown effect of multidomain grains in Le Goff–Gallet method
Multispecimen (Hoffman et al. 1989)	Hoffman and Biggin (2005); Dekkers and Böhnelt (2006); Fabian and Leonhardt (2010)	Fast; <i>inter</i> -specimen consistency is implicitly considered; domain state effects can be minimized in Dekkers–Böhnelt experiments; fewer heating steps implies less alteration	Fewer checks for <i>intra</i> -specimen consistency; no internal checks for alteration; domain-state benefits of Dekkers–Böhnelt method may be lost if secondary magnetizations require removing (Michalk et al. 2010); original Dekkers–Böhnelt method may not be domain state independent, but can be corrected (Fabian and Leonhardt 2010)
Calibrated pseudo-Thellier	Stephenson and Collinson (1974); de Groot et al. (2013); Paterson et al. (2016)	No heating required; fast, especially on automated systems	ARM/TRM ratio is grain size dependent, which manifests as a ~ 25% uncertainty on the calibration factor (Paterson et al. 2016)
IRM Normalization (Cisowski and Fuller 1986)	REM (Kletetschka et al. 2000); REM (Gattacceca and Rochette 2004)	No heating required	Precision limited to orders of magnitude
First-order reversal curve (FORC)	Muxworthy and Heslop (2011); Muxworthy et al. (2011); Di Chiara et al. (2017)	No heating required; moderately fast	Limited testing; considered accurate to a factor of 2–3

in nature and which therefore possess a TRM imparted by the ambient (geomagnetic) field. Materials that may be used include any fired archaeological materials (ceramics, kiln lining, hearths, burnt bricks, etc.) and most types of igneous rocks.

Producing unequivocally accurate measurements of the absolute palaeointensity is extremely demanding and requires at least the following:

1. The remanence carriers must retain a pure TRM and have undergone no chemical or physical changes since cooling beneath their Curie temperature (see e.g., Fabian 2009).
2. Any secondary components of magnetization (e.g., viscous or isothermal overprints, see ► “[Remanent Magnetism](#)”) must be removed so that the primary TRM is isolated.
3. The remanence carriers must undergo no chemical or physical alteration as a consequence of the laboratory heating that it is required to obtain the palaeointensity (or this must be corrected for; see e.g., Valet et al. 1996).
4. It must be shown that multidomain, vortex state, or magnetically interacting grains are not biasing the measurement by violation of Thellier’s laws of thermoremanence (see ► “[Remanent Magnetism](#)”).
5. Any anisotropy of TRM must be avoided or corrected for (see e.g., Veitch et al. 1984).
6. Any effect that the difference in the cooling rate between the natural and laboratory cooling cycles has on the magnitude on the calculated palaeointensity must be corrected for (see e.g., Perrin 1998).
7. Any deviation from Thellier’s law of linearity must be detected and corrected for (Selkin et al. 2007).
8. The number (N) of individual sample estimates from a single rock unit or archaeological horizon must be *sufficient* to obtain a reasonable mean (μ) and to demonstrate *adequate* internal consistency (see e.g., Paterson et al. 2010).

The high failure rates and time-consuming nature of many absolute palaeointensity studies have stimulated a wealth of innovation in terms of both the types of materials that are used and the manner in which the experiments are performed. In the former respect, two noteworthy materials are submarine basaltic glass (SBG) generally taken from ocean drilling cores and ophiolites (Tauxe 2006), and single silicate crystals isolated from both extrusive and intrusive rocks (Tarduno et al. 2006). Both of these have been argued to be higher fidelity recorders (less prone to problems numbered 1, 4, and/or 6 in the list above) than more conventional palaeointensity recorders (e.g., whole-rock subaerial lava samples). As an alternative approach to favoring any one specific recorder, the Q_{PI} criteria (Biggin and Paterson 2014) were developed as a universal qualitative measure of palaeointensity reliability. These attempt to emulate the success of a similar tool (Van der

Voo 1990) long-applied to palaeomagnetic poles in deriving a set of qualitative “check boxes” for minimizing the risk of bias associated with any of the problems listed above.

In terms of the techniques developed to measure the absolute palaeointensity, Table 1 summarizes some of those which are more widely used and provides the relevant references. The Thellier method and its derivatives remain the most widely used and trusted technique; for more information on this and other techniques listed in Table 1, the reader is directed to comprehensive reviews by Tauxe and Yamazaki (2015) and Valet (2003). Accompanying these techniques is a broad range of statistics that are used as selection criteria to screen less reliable results. For a comprehensive description of these statistics and comparisons of the effectiveness of various sets of selection criteria, see Paterson et al. (2014, 2015).

Relative Palaeointensity Measurements

Palaeomagnetic analyses of sedimentary rock and soft sediment samples can produce continuous time series of geomagnetic intensity variations which may be calibrated using absolute palaeointensity estimates or used alone as records of geomagnetic behavior. Relative palaeointensity studies are generally undertaken on the assumption that the samples retain a DRM acquired as the magnetic grains in the sediment physically align themselves during or shortly after deposition from the water column. The DRM acquisition process is sensitively related to the size, shape, and composition of the remanence carriers and is further complicated by flocculation effects in saline environments. Much later, the intensity of the magnetization can be significantly affected by consolidation and compaction processes (see review of Tauxe and Yamazaki 2015).

Some normalization of the measured magnetization intensity is required to account for changes in the concentration and nature of the magnetic recorders (which should ideally be small) and produce a record of geomagnetic intensity variations. Candidates for normalization include ARM, IRM, and low-field susceptibility. These should ideally display a strong coherence with the NRM signal (after removal of any secondary components of magnetization), but no coherence with the normalized record (Valet 2003). The reliability of a relative palaeointensity record can be further supported by the presence of antipodal directions (indicating no inclination flattening) and by the coherence of multiple curves from the same region covering over the same time interval (as calibrated using independently obtained timescales).

The sedimentation rate and the interval over which the magnetization is “locked-in” obviously set a limit on the time resolution of any relative palaeointensity record. In deep-marine sediments, a standard 2.5-cm palaeomagnetic

sample can represent a time period of 10 kyr or more, which will produce significant smoothing of secular variation (see ► “[Geomagnetic Field, Secular Variation](#)”). Roberts et al. (2013) provide a detailed discussion of DRM processes, relative paleointensity determinations, and normalization techniques.

Cosmogenic Isotope Palaeointensity Measurements

This method of palaeointensity measurement, applicable to the last few hundreds of kyr, is based on the fact that production rate of certain radioisotopes (^{14}C , ^{36}Cl , and ^{10}Be) is strongly influenced by the degree of shielding the geomagnetic field provides the Earth from incoming cosmic rays. Records of the concentration of these isotopes in sediment and ice cores (and tree rings and corals in the case of ^{14}C) can therefore provide a proxy for geomagnetic dipole moment once the necessary corrections for latitude and relevant physical, chemical, and biological processes have been made. See review by Valet (2003) for more information.

Geophysical Applications

Palaeointensity measurements provide information about the geodynamo across a variety of time scales. Since direct observations of field strength were first made in the 1830s, the main axial dipole field has fallen by around 10%. The rate and duration of this dipole decay is a focus of many archaeointensity studies, but is still debated. Using VADM values derived directly from archaeointensity estimates, Poletti et al. (2018) suggest that the dipole intensity has been decreasing since ~750 CE – over a millennium of weakening. Recent studies based on global field models (e.g., Arneitz et al. 2019; Hellio and Gillet 2018), however, argue that the axial dipole has been weakening only for the last few centuries with variable trends prior to this.

Archaeointensity and absolute palaeointensity data are particularly important for constructing global field models, which now extend to 100 ka (Panovska et al. 2018). Each of the observable palaeomagnetic field components (declination, inclination, and intensity) can be mapped, via their respective Green’s functions, to the radial field at the core mantle boundary (Johnson and Constable 1997). Measurements of field intensity yield different information than directional data about the core mantle boundary (particularly at higher latitudes; Johnson and McFadden 2015).

Relative palaeointensity records from varved sediments are capable of providing good temporal resolution over the Holocene and agree well with absolute intensity records as well as records of cosmogenic nuclide production (Snowball and Sandgren 2002). Correspondingly, absolute archaeointensities

have been combined with the ^{14}C record from tree rings and the ^{10}Be record from ice-cores to infer variation in solar activity, with implications for understanding solar forcing of climate (Solanki et al. 2004). Marine sediments can provide relative palaeointensity records over longer timescales. Here it is usually assumed that a typical sample will represent a sufficiently long period for non-dipole features to be averaged out (Valet 2003) allowing composite stacks of relative palaeointensity from different areas of the world to be constructed. A global stack for the past 2 Myr, Sint 2000 (Valet et al. 2005), agrees well with absolute palaeointensity from lava flows and confirms a low field strength during excursions. This has been incorporated into a continuous model of axial dipole moment variation for the past 2 Ma (Ziegler et al. 2011). Importantly, this record is long enough to include reversals and finds a correlation between polarity interval length and field strength. This same correlation is seen, albeit weakly, in the 11 Myr Oligocene record from site Deep Sea Drilling Project, site 522 (Constable et al. 1998) and in SBG absolute intensity records (Tauxe 2006).

It becomes increasingly difficult to obtain relative palaeointensities from sediments more than a few million years old so longer term variations in field strength are studied using absolute palaeointensity derived from igneous rocks. The emerging picture characterizes the time-averaged dipole moment over the last few hundreds of millions of years as substantially lower than its current instantaneous value, but subject to dramatic variations on timescales ranging from centennial or shorter to at least hundreds of millions of years (Biggin et al. 2012; Tauxe and Yamazaki 2015).

Prévot et al. (1990) found evidence of a long period of low field intensity which they called the *Mesozoic dipole low*. However, subsequent work (Kulakov et al. 2019; Tarduno et al. 2006; Tauxe and Staudigel 2004) has indicated that this did not extend into the Cretaceous normal superchron (CNS; 84–121 Ma) and its age of onset remains unclear (Anwar et al. 2016). Other notable lows have recently been identified in the mid-Palaeozoic (Hawkins et al. 2019) and Ediacaran (Bono et al. 2019). The timing of these lows, on the order of 200 million years apart, together with a similar temporal variability seen in Phanerozoic polarity reversal frequency (the dipole lows being coincident with inferred intervals of reversal hyperactivity) gives rise to the hypothesis that dipole moment is quasi-periodic on these long timescales. The likely candidate for the source of such variations is changes in the total heat flowing across the core-mantle boundary and/or its spatial pattern, which might themselves be linked to substantial fluctuations on similar timescales in the global flux of slab material subducted into the mantle (Hounslow et al. 2018).

Claims of even longer, billion-year variations in dipole moment linked to the secular evolution of the core (including inner core nucleation) and mantle remain controversial (Biggin et al. 2015; Bono et al. 2019; Smirnov et al. 2016; Tarduno et al. 2015). Similarly, the magnitude and

timing of the expected variations under different core thermal evolution scenarios is not yet clear (Driscoll 2016; Landeau et al. 2017). Vigorous activity in this potentially fruitful research area is anticipated for years to come.

Palaeointensity experiments are not confined to terrestrial rocks, with numerous studies on lunar, Martian, and meteorite materials. Lunar regolith from the Apollo missions is thought to hold a thermoremanence and a variety of palaeointensity techniques suggest a strong dynamo (20–100 μT) operating between ~ 4.2 and ~ 3.6 Gyr (Cournède et al. 2012; Suavet et al. 2013), prior to a possible prolonged period of weak field (~ 5 μT) that extended to at least ~ 2.5 Ga (Tikoo et al. 2017). Martian meteorites have been used to estimate the ancient Martian field (Shaw et al. 2001; Weiss et al. 2008b), and paleointensity studies on pallasite meteorites indicate that small (~ 200 km) planetesimals are also capable of sustaining dynamo-generated magnetic fields with field strengths of ~ 30 – 130 μT (Bryson et al. 2015; Tarduno et al. 2012). Some of the most ancient meteorites, formed at the onset of our solar system, are also capable of remembering magnetic fields in the solar nebula, yielding insight into solar system evolution (Wang et al. 2017; Weiss et al. 2008a).

Summary

From 450-year-old pots to 4.5 billion-year-old meteorites, studies on the strength of Earth's ancient magnetic field continue to flourish, bringing with them new innovations in methods, materials, and analyses. And as paleointensity studies grow, we are gaining new understanding on the evolution of the magnetosphere in near-Earth space, the planet beneath our feet, and the solar system beyond.

Paleomagnetism, Magnetostratigraphy

Donald R. Prothero

Department of Geology, Occidental College, Los Angeles, CA, USA

Synonyms

Magnetic polarity stratigraphy; Magnetic stratigraphy

Definition

- | | |
|-----------------------|---|
| Magnetic stratigraphy | Application of magnetic methods to obtain the magnetic polarity pattern in stratified rocks, allowing them to be correlated to the global magnetic timescale. |
| Remanent magnetism | Permanent magnetism in rocks, caused by the orientation of the Earth's magnetic field at the time the rock was formed. |

Magnetic Stratigraphy

Introduction

Since the 1960s, one of the most important tools for dating and correlating fossiliferous sedimentary rocks has been magnetic stratigraphy. First developed to aid in the correlation of deep-sea sediment cores from the Deep Sea Drilling Project, by the 1970s it had also been applied to dating terrestrial sedimentary rocks as well. The early efforts were hampered by the slowness and insensitivity of old spinner magnetometers, but with the widespread availability and the increased reliability, sensitivity, speed, and precision of cryogenic magnetometers in the 1970s, the field has grown tremendously. It has now been applied to many of the important marine and terrestrial sequences that were the type sections for biostratigraphic zones and timescales, and is routinely used whenever there are suitable outcrops and age control to allow global correlation.

Magnetic stratigraphy works by obtaining a dense sampling of oriented samples from stratigraphic sections of layered sedimentary rocks or volcanic rocks. These samples record the direction of the magnetic field (*normal*, as in today's field, or *reversed*, about 180° from today's field) in a random pattern of polarity zones. If there is a sufficiently long pattern of polarity zones, it can be matched up to the global magnetic polarity timescale by calibrating it with radiometric ages, or by means of biostratigraphy, or both. Once sections have been correlated, the magnetic polarity

reversals represent time planes, and their ages can be resolved to less than 10,000 years, much better dating and resolution than obtainable by any other means.

Detrital Remanent Magnetization

Although it is possible to correlate lava flows by magnetic methods, by far the most common application of magnetic stratigraphy is to layered sedimentary rocks. These rocks become magnetized by *detrital remanent magnetization* (DRM). When the sediment is loose and fluid, it will contain a small number of tiny (less than 60 μm in diameter) grains of magnetic minerals, such as magnetite or hematite. While these sediments settle out and become liquefied, the magnetic mineral grains are influenced by the ambient magnetic field at the time the sediment was deposited, and thus line up to be parallel to it. Thus, the magnetic grains act like tiny bar magnets, or like iron filings near a bar magnet. As the sediment becomes compacted or cemented and turned into sedimentary rock, the orientation of these magnetic grains is preserved. Although there are instances of sediment compaction causing the grains to rotate and thus flattening the inclination angle, most sedimentary rocks seem to record field directions that closely match those produced from the cooling of igneous rocks, which are not subject to compaction (Butler 1992, pp. 183–187).

Field and Laboratory Techniques

In order to undertake a magnetostratigraphic study, a large number of oriented samples densely spanning the total stratigraphic interval of exposed rock are required. The density of sampling is dictated by how many exposures are suitable, and the logistics of how many people and man-hours of field work are available to conduct the sampling, since it is a tedious and exhausting task. Typically, each stratigraphic level or “site” is sampled at least in three places, and more if possible, so that Fisher statistics can be calculated. In deep-sea cores, sampling is conducted on the split core, with small subsamples taken from the core so that an excessive amount of material is not removed.

The lithology of rock is also critical. Most remanence is held in tiny (less than a few tens of microns) *singledomain grains* of magnetic mineral, or in slightly larger *pseudo-single domain* grains. Above a certain size, it is possible to have two or more magnetic domains in a grain, and then they will tend to form antipodally oriented domains within a single grain and cancel each other out, giving no net remanence. Thus, a fine-grained component is essential for a sedimentary rock to retain useful remanence. For this reason, sampling usually concentrates on shales, mudstones, and fine-grained

sandstones. Coarser sandstones may work if they have a fine-grained matrix. A well-sorted, very clean coarse sandstone with no matrix should be avoided for this reason.

If the rocks are very hard and well cemented, it is possible to sample using a coring drill, as is commonly practiced in igneous and metamorphic rocks. Most sedimentary rocks, however, are too friable and crumbly to stand up to the stress of drilling and the flow of water through the drill bit (required to cool the bit and flush out the drilled rock chips). In this case, samples of terrestrial rocks are taken by scraping oriented surfaces on hand samples, and then subsampling them into cubes or cores in the laboratory using a coring drill or band saw, or hammer and sandpaper for very soft rocks. If the samples are very friable (such as loose soils or unconsolidated sediments), it is still possible to obtain oriented samples. Typically, this is done by pressing open tubes of a high-temperature glass (such as quartz glass or sometimes Pyrex) into the exposure, measuring the orientation, then removing it and pouring a high-temperature-tolerant hardener (such as sodium silicate) into the sediment. The tube is then taped shut, and in the lab it can be sealed at the open end by a high-temperature ceramic, such as Zircar aluminum cement. The sealed glass tube is then measured as if it were a normal drill core. In addition, samples may crumble during preparation until they are too small for a core or cube. They can be salvaged by placing them oriented face down on a piece of wax paper, surrounding them with a plastic ring the diameter of a core (such as a cut piece of plastic test tube), and pouring in Zircar aluminum ceramic to make them into a molded ring that will survive the high temperatures of the thermal demagnetization.

Once samples are fully prepared, they can be measured in a magnetometer to determine the direction and intensity of their magnetic remanence. Before the late 1970s, all the studies were done with older-generation *spinner magnetometers*, which required over 30 min to measure a single sample, and were not sensitive enough to measure most sedimentary rocks. For this reason, only a few measurements could be made on each sample, and only a limited number of samples could be taken if the project were to remain reasonable in size.

In the 1970s, the invention and widespread adoption of *cryogenic magnetometers* revolutionized the study of paleomagnetism. These devices have a sealed jacket of liquid helium at 4 K surrounding a superconducting region in the bottom of the magnetometer. The electronics in the cryogenic chamber are thus sensitive to extremely small magnetic moments, and can make measurements in a few seconds. They are four to five orders of magnitude more sensitive than spinner magnetometers, so samples can be measured that are extremely weakly magnetized. These include not only every kind of rock but even organic tissues like the magnetite in bacteria or birds or bees or butterflies. Early cryogenic magnetometers were very temperamental and

prone to problems. They bled off the evaporating helium at such a fast rate that a single shipment costing hundreds of dollars would only last a few weeks. Only a few measurements could be taken on each sample, and the lab had to work 24/7 to use every precious second of magnetometer time. Now most cryogenic magnetometers have a cryocooler pump that circulates liquid helium or nitrogen around the cryogenic container, and keeps it cold for many months at a time, greatly reducing the cost of operation, wear and tear on the magnetometer, and improving reliability. In many labs (especially those equipped with a Caltech-style automatic sample changer), it is possible to make dozens of measurements in an hour, allowing paleomagnetists to make dozens of different measurements on each sample.

Each sample contains a mixture of remanences acquired during the long history of the rock unit. There will be a primary, or characteristic, component from when the rock originally formed, which may be overprinted by one or more magnetizations that were acquired at later times. For a reliable paleomagnetic study, the researcher must attempt to remove these overprinted components by gradually demagnetizing the sample, and gradually stripping off the younger, less stable magnetizations until only the characteristic remanence is left. Consequently, it is typical for a modern paleomagnetic study to measure the samples first at NRM (*natural remanent magnetization*, or the magnetization of the sample before treatment). The samples can then be demagnetized using *alternating fields* (AF), which helps remove remanence due to low-coercivity minerals such as magnetite, and eliminates magnetization from transient fields (such as lightning strikes) or from VRM (*viscous remanent magnetization*). Examination of the magnetic behavior and the drop in intensity at each AF step allows the paleomagnetist to determine how much of the remanence is held in a low-coercivity mineral, or whether significant high-coercivity minerals (which do not respond to AF demagnetization) are present. AF treatment is usually sufficient for samples from deep-sea cores, which have not undergone any significant diagenesis or alteration. Another method, known as *thermal demagnetization*, heats the samples in field-free space to a preset temperature, then cools them down to room temperature without acquiring any new magnetization from the earth's field. In some cases, the oven is saturated by a jet of nitrogen gas to reduce the possibility of minerals oxidizing as they cool down. Thermal demagnetization in many steps of increasing temperature allows the paleomagnetist to see how the remanence changes as higher and higher temperatures are reached and the *blocking temperature* of the magnetic minerals (578 °C for pure magnetite; 630° for hematite) is approached. At high temperatures, the behavior of the sample above the blocking temperature of magnetite tells the researcher about the intensity and direction of the magnetic components that are held in hematite. Thermal

demagnetization has an additional advantage. Above 200 °C, iron oxides and hydroxides such as goethite are converted to hematite, and their remanence is removed. These “rusty” minerals are often formed by weathering of sedimentary rocks at the surface, and usual form as a *chemical remanence* deposited in the rock long after the primary or characteristic remanence was formed. Thus, they are a form of overprinting that must be removed, but cannot be affected by AF demagnetization. For this reason, nearly all terrestrial sedimentary rocks (even if they are not visibly reddish) should be thermally demagnetized to insure that there are no false overprinted magnetic components. Many studies use both AF and thermal demagnetization on every sample to strip off overprints due to iron oxides, to determine the relative contribution of high-coercivity and low-coercivity minerals, and to obtain a clear sense of the dominant magnetic mineralogy of each sample. The samples can also be studied in polished thin sections, where the light reflects differently off magnetite, goethite, and hematite, and the depositional fabric of the magnetic mineral and size of the grains can be determined.

These magnetic directions can be plotted and analyzed in a number of different ways. For simple visual plotting of the three-dimensional changes in directions, a conventional *stereonet* can be used. But a stereonet only shows direction, where as an *orthogonal demagnetization plot* (“Zijderveld plot”) shows both the direction and intensity of each demagnetization step (Zijderveld 1967). Most paleomagnetics labs have software that rapidly creates these plots, so the behavior of the sample can be studied as the demagnetization proceeds. Once a stable remanence has been obtained and overprints isolated and removed, the inferred characteristic remanence components are usually summarized by the *least squares method* of Kirschvink (1980). These directions for each sample can then be averaged using Fisher (1953) statistics, which give the mean and ellipse of 95% confidence for each sample. Using Watson's (1956) criteria, the statistical significance of each site can be assessed. Frequently they are ranked using the criteria of Opdyke et al. (1977), where Class I sites are statistically significant at the 95% confidence level, that is, there is a 95% chance that the sample distribution differs from a random distribution. These sites were labeled “Class A” by Johnson et al. (1985). Class II sites have fewer than three samples (so statistics cannot be calculated), and Class III sites (“Class B” sites of Johnson et al. 1985) have at least two sample directions that are in agreement, but one which is divergent due to incomplete removal of overprints. These directions can then be plotted against a stratigraphic column to show the overall polarity pattern for the section, and also indicate the degree of reliability of individual samples at each site.

As in any other paleomagnetic study, there are a number of techniques for assessing the stability and reliability of the sample directions (see Butler 1992, pp. 123–128). The most commonly used in magnetostratigraphy is the *reversal test*,

which compares the statistical mean of all normal directions and reversed directions to see if they are antipodal (as they should be if they represent the original magnetic field of the earth). Most long stratigraphic sections yield both normal and reversed polarity samples, providing the data for a stability test like this. In some cases, there are conglomerates in the section, so a *conglomerate test* can be performed. In this test, samples are taken from a large sample of clasts in a conglomerate. If their directions are randomly scattered, then they have not been remagnetized since the conglomerate formed. If, on the other hand, they yield directions that are clustered, then there has been overprinting not only of that conglomerate, but also of the rocks in the rest of the section. Another common test in rocks that have been deformed is the *fold test*. The researcher can compare the directions of the samples with and without dip correction. If these directions are clustered with dip correction, and more scattered without dip correction, then the directions were acquired before folding. If the directions are more clustered in their uncorrected, folded orientation, then the directions were acquired after folding (and thus are not primary or characteristic directions). Not all these stability tests are available in every study, but at least one (usually the reversal test) should be attempted to obtain credible results. If other tests are also available, they should also be analyzed to increase the rigor of the study.

Calibration and Correlation

Once characteristic directions that have passed stability tests have been obtained from each site and they are plotted, then the overall polarity pattern for each individual section can be assessed. Polarity zones are not diagnostic or unambiguous by themselves, but must be correlated based on other criteria, such as lithostratigraphy or biostratigraphy. In the early days of magnetic stratigraphy, deep-sea cores (Fig. 1) could be sampled down from the modern sediments at the top of the core, and each polarity zone could be calibrated by the Brunhes normal polarity magnetozones at the top. Most deep-sea cores, however, do not have a continuous sedimentary record from the present backward, but represent an older geologic span of time separated by unconformities. In such cases, the biostratigraphy of the planktonic microfossils enables the scientist to calibrate a core directly against the magnetic polarity timescale.

In another example, Fig. 2 shows the correlation of magnetozones of many different stratigraphic sections across the Eocene-Oligocene White River Group from northeastern Colorado to Nebraska and Wyoming to the Big Badlands of South Dakota to North Dakota. The correlations are based on the lithostratigraphic units and the biostratigraphic zonation, with the common datum based on a widespread ash horizon found throughout most of the sections. Note that the polarity

magnetozones are roughly consistent in thickness from one section to another, although each of the magnetozones is proportionally thicker where the total sediment accumulation rate is higher (e.g., Slim Buttes, South Dakota).

But these polarity matches do not establish correlation with the global magnetic polarity timescale. Magnetic polarity can only be “normal” or “reversed,” and that pattern has occurred thousands of times in the geologic past, so it is not sufficient just to get a raw polarity pattern and attempt to correlate it to the global timescale (unless you are working down from modern sediments at the top of a section, in which case the uppermost normal magnetozones is the Brunhes Chron, or Chron 1n). For reliable correlation, the section needs to be calibrated by some sort of independent means of time control. Ideally, this is provided by at least one and preferably more radiometric dates, which will place the local section on the global magnetic polarity timescale (Fig. 3). Where radiometric dates are not available, it is often possible to use a finely resolved well-calibrated biostratigraphy (whose precise correlation to the global timescale is already known) to correlate another section containing those key fossils.

Strengths and Weaknesses of Magnetic Stratigraphy

Like any other stratigraphic technique (see Prothero and Schwab 2003), magnetic stratigraphy has great strengths – and also some weaknesses. The strengths include:

1. *Worldwide*: magnetic polarity events happen around the globe simultaneously. By contrast, most other stratigraphic markers (volcanic ashes, biostratigraphic events, lithologic boundaries, even isotopic events) occur only locally.
2. *Independent of facies or lithology*: any fine-grained sedimentary rock or volcanic rock will work, allowing us to correlate between deep-sea muds to shallow-marine silts to terrestrial floodplain mudstones. By contrast, rock units are typically time-transgressive as facies migrate, and are not found on both land and sea. Stable isotope curves are usually restricted to marine rocks.
3. *Geological instantaneous*: polarity reversals take place over 4000–5000 years, which is a geological instant for most studies of the deep past. By contrast, most lithostratigraphic units are time-transgressive over millions of years.
4. *Constant resolution regardless of age*: the duration of magnetic polarity transitions is constant whether the rocks are Pleistocene or Permian, so the resolution is always in the order of a few thousand years.

By contrast, radiometric dates have an error bar that is a proportion of the mean age and therefore gets larger as the rock gets older. For example, if the error estimates are $\pm 5\%$

Paleomagnetism, Magnetostratigraphy, Fig. 1 Magnetostratigraphic correlation of Antarctic cores, based on the modern Brunhes normal polarity sediments at the top of each section, and the biostratigraphic zones of radiolaria (shown by the capital Greek letters) in each

core. To the right of each column, minus signs indicate normally magnetized specimens, while plus signs are reversed specimens. (After Opdyke et al. 1966, Fig. 1; by permission of the American Association of the Advancement of Science)

for a rock of 1 Ma, then the true age is 1 million $\pm$ 50,000 years. If the age is 100 Ma, however, then the true age is 100 million $\pm$ 5 million years. In other words, there is a 95% probability that the true age lies between 95 and 105 Ma. These error bars get larger with older and older rocks.

There are some limitations to magnetic stratigraphy as well:

1. Only *finer-grained lithologies*, or sandstones with clay matrix, are suitable (as discussed above).
2. If there are *unconformities* in the section, then magnetostratigraphic zones can be shortened or deleted altogether. This problem can best be addressed by biostratigraphic methods, the usual way in which we test for evidence of slow or no deposition.

3. *Demagnetization problems* can hamper the quality of the data, particularly in yielding spurious normal overprinted zones that have not yet been removed by thermal demagnetization of iron oxides and hydroxides (e.g., Butler and Lindsay 1985).
4. *Independent form of age control* is required to calibrate the section.

Some Applications and Implications

Since the late 1960s, magnetic stratigraphy has become one of the most powerful tools available for precise dating of sedimentary sequences and geologic events, and for correlation of events between the terrestrial, shallow-marine, and deep-sea

Paleomagnetism, Magnetostratigraphy, Fig. 2 Correlation of magnetostratigraphic sections in the White River Group from North and South Dakota. All of the sections are correlated based on the datum of the base of the Orellan. Abbreviations as follows:

NALMA = North American land mammal ages; LN = Lower Nodular Zone of the Big Badlands; RFA = Rockyford Ash. (From Prothero (1996, Fig. 9))

records. In most detailed stratigraphic studies, it is routine to do magnetostratigraphic analysis along with biostratigraphy to form a network of correlation now called *magnetobiostratigraphy* (Fig. 4). Combined with stable isotope stratigraphy (especially in deep marine cores), it is possible to obtain very high-resolution, high-precision dating of many stratigraphic sections and correlate their events with high precision on a global basis. This, in turn, has allowed reliable and detailed comparison between climatic and biotic events on the land and the sea, and has revolutionized our understanding of climatic change and global correlations of climate and evolution.

The application of magnetic stratigraphy has also changed our conceptions of many geologic problems. For example, the dating of strata before the advent of magnetic stratigraphy has been radically rethought as these correlations improve. In North America, for example, the Uintan and Duchesnean land mammal ages of Wood et al. (1941) were once thought to be late Eocene, the Chadronian land mammal age early

Oligocene, and the Orellan and Whitneyan land mammal ages middle and late Oligocene, respectively. However, with the advent of magnetobiostratigraphy and high-resolution argon/argon dating, all these correlations have changed radically (Prothero and Swisher 1992). The Uintan and Duchesnean are now middle Eocene, the Chadronian late Eocene, and the Orellan and Whitneyan early Oligocene. The Arikarean, once thought to be early Miocene, is now largely late Oligocene. Every one of the original mid-Cenozoic stratigraphic interpretations of the Wood Committee (1941) was mis-correlated to the standard European timescale by at least one stage of the Eocene or Oligocene (and the same was true of their North American Miocene-Pliocene stages). Prior to magnetic stratigraphy and radiometric dating, the Desadean land mammal age of South America was thought to be early Oligocene (27–37 Ma). Today it is considered late Oligocene to early Miocene (22–27 Ma) in age (MacFadden et al. 1985), or about 10 million years younger than originally thought.

Paleomagnetism, Magnetostratigraphy,

Fig. 3 Calibration of the White River-Arikaree Group magnetic stratigraphy of Fig. 2, based on $^{40}\text{Ar}/^{39}\text{Ar}$ dating of key volcanic ashes. Abbreviations: BR = Bracks Rhyolite; BU = Buckshot Ignimbrite; LWA = Lower Whitney Ash; NPAZ = Nonpareil ash zone; RRA = Roundhouse Rock Ash; UWA = Upper Whitney Ash. (Modified from Prothero and Swisher 1992, Fig. 2.3)

Magnetic stratigraphy has also been used as a device for testing other geologic ideas. Because it produces geologically instantaneous time planes, it is valuable in testing whether biostratigraphic datums are synchronous or not. By and large, this has proven true, confirming the importance of biostratigraphy as a time indicator. Prothero (1982) showed this in the Eocene-Oligocene strata and fossils of the White River Group of the American High Plains. Lindsay et al. (1984) did the same for the biostratigraphy of the late Cenozoic of southwestern North America and Europe, as did Flynn et al. (1984) for the Eocene of the Rocky Mountains. A few biostratigraphic events, like *Lepus* event in North America (Lindsay et al. 1990), or the *Hipparion* horse datum in Europe, are demonstrably time-transgressive (Woodburne et al. 1981; Woodburne 1989), but these are the exceptions to the rule.

In some cases, magnetic stratigraphy produces powerful inferences about the rock record. For example, Johnson et al. (1975) showed that magnetozones could be mapped along the Miocene-Pliocene exposures in the San Pedro Valley of Arizona. These “invisible magnetic time planes” (Fig. 5) exist in the outcrops and can be mapped and interpreted using

standard magnetostratigraphic methods. Magnetic stratigraphy allows precise determination of sedimentation rates in marine and terrestrial sections, and relative completeness of sections, which are important to many different kinds of stratigraphic studies (Sadler 1981; May et al. 1985; Johnson et al. 1988).

Summary

Magnetic stratigraphy is now one of the principal tools that allow the precise, high-resolution correlation of geologic events in the stratigraphic record, especially climatic events. It is unique among stratigraphic methods in that global high-resolution correlations are possible between terrestrial and marine records, and does not suffer from issues of local facies changes or limited lateral extent of most other stratigraphic markers. Of course, the researcher must be aware of the limitations: relatively complete well-exposed sections of fine-grained rocks are required, as is an independent form of time control to allow calibration. Every sample must be

Paleomagnetism, Magnetostratigraphy, Fig. 4 Magnetostratigraphic correlation of marine sections from the Pacific Coast, based on the magnetic polarity pattern and the biostratigraphy of

microplankton. On the left is the standard geological time scale and polarity chrons with the planktonic zones of nannofossils and foraminifera. (After Prothero 2001)

Paleomagnetism, Magnetostratigraphy, Fig. 5 Topographic profile across the San Pedro Valley of Arizona, showing the interpretation of “invisible magnetic zones” lying within the outcrops based on the sampling of Johnson et al. (1975). (Modified from Johnson et al. 1975, Fig. 8)

carefully analyzed by multiple techniques to insure that the primary or characteristic remanence has been recovered and overprinting removed. Nonetheless, magnetic stratigraphy has improved our correlations of global events by several orders of magnitude, and corrected many erroneous correlations that were once widely accepted. It has allowed for many other interesting studies, such as analysis of rates of sedimentation, and tests of the isochroneity of biostratigraphic events. In short, the horizon is limitless for the application of paleomagnetism to stratified rocks.

Ancient magnetism; Fossil magnetism

Definition

Palaeomagnetism is the study of the Earth's magnetic field in past times. A permanent record of the ancient magnetic field is recorded by certain ferromagnetic minerals contained in rocks either precipitated as primary crystals, or as secondary alteration products formed during later geological events. The ancient direction of the geomagnetic field can be readily determined from this record, and the time of acquisition can usually be dated when carefully related to the geological history. The information is essential for quantifying motions of the tectonic plates comprising the outer shell of the Earth and resolving the nature of global tectonics in past times. The ancient intensity of the field is a more challenging parameter to resolve, but is key to resolving the long-term history of the geodynamo, while techniques for recovering it are improving all the time. Although this contribution is concerned primarily with the record of fossil magnetism in the rock record and the means of determining it, the acquisition of magnetism is an ongoing process within materials forming at the present day. In addition to continuing igneous activity and sedimentation, it is acquired, for example, by diagenetic processes in soils and by the secretion of magnetotactic bacteria within living things.

Introduction

The permanent magnetism residing in a natural material, lodestone containing the mineral magnetite (Fe_3O_4), has been known for many centuries for its ability to align with the polar direction and has long been used for this purpose by navigators. It was originally believed that the pole star (Polaris) or a large magnetic island at the North Pole attracted lodestone compasses. However, William Gilbert (1544–1603)

in his book *De Magnete, Magneticisque Corporibus, et de Magno Magnete Tellure* published in 1600, concluded that the Earth behaved like a giant magnet. He argued that the center of the Earth was iron. His other important achievement was documenting the special property of magnets by showing that they could be cut so that each new magnet possessed north and south poles. By the nineteenth century, it had been discovered that certain rocks were capable of becoming permanently magnetized in the direction of the ambient geomagnetic field. Bernard Brunhes (1867–1910) found young volcanic lavas in central France magnetized in a direction opposite to the prevailing field. This is the phenomenon of geomagnetic reversal, and in 1929 Japanese scientist Motonori Matuyama (1884–1958) was able to show that reversals of the field appeared to have occurred at specific times during the recent geological past.

The geometry of the magnetic field direction at the surface of the Earth is described in terms of declination and inclination. *Declination* refers to the angle in the horizontal plane between geographic north and the geomagnetic direction along which the lines of magnetic field are directed. Since the magnetic field is also directed towards, or away from, the source within the Earth (with the exception of the magnetic equator), it is typically inclined to the horizontal; the angle above (negative) or below (positive) the horizontal is the *inclination* of the field. In the characteristic surface expression of an inner dipole source, it will be latitude-dependent and range smoothly from vertically up or down at the magnetic poles through zero at the equator.

A geocentric dipole source with an axis aligned to geographic north-south rotation axis is the model used for relating a palaeomagnetic direction to a pole position relevant to unraveling ancient continental movements. For this assumption to be true, it is important to demonstrate that the magnetic poles are always constrained to the geographic poles of rotation in the long term. Historic records of the magnetic field recorded in London from 1580 show that the declination of the magnetic field changed from 11°E to 24°W by 1820 with the calculated position of the magnetic pole executing a path around, and close to, the geographic pole of rotation. This movement is *secular variation* and when time-averaged the migration of the magnetic pole proves to be very close to the geographic pole. Subsequent analyses found that Late Tertiary palaeomagnetic poles, a time interval over which continental motions had been relatively small, yielded magnetic pole estimates very close to the pole of rotation when averaged over intervals of thousands of years. In 1926 this led P-L Mercanton (1876–1963) to suggest that fossil magnetism could be applied during more ancient times to monitor movements of the continents.

An outcome of magnetic research conducted during World War II was the development by Patrick Blackett (1897–1974)

of a sensitive astatic magnetometer able to accurately measure magnetism in relatively weakly magnetized materials such as rock samples. It was first employed from the early 1950s by Patrick Blackett and Keith Runcorn (1922–1995). Analysis of the evidence, particularly by the seminal work of Edward Irving (1927–2014), showed that the continents had moved over the surface of the Earth in ways that matched movement through latitude conforming to ancient climatic evidence from the source rocks. This evidence placed the theory of continental drift, which had languished since proposed by Alfred Wegener (1880–1930) in 1915, onto a firm quantitative basis. When it was realized that the ocean crust could also preserve a palaeomagnetic record from the time of its formation, continental drift was rapidly integrated with the temporal evidence from the magnetic lineaments defining crustal growth of the ocean floors (sea floor spreading). This provided the key quantitative evidence for the Theory of Plate Tectonics in the 1960s, a theory formally articulated in 1967. The Plate Tectonic paradigm accommodated extensive additional evidence from earthquake and volcanic activity and has prevailed with much refinement, as the explanation for the growth and destruction of Earth's surface plates up to the present day. Palaeomagnetism has thus provided the primary data for quantifying the rate of plate movements and remains one of the most important techniques in the Earth Sciences. It is also versatile and has applications to many other fields including environmental sciences and archaeology.

In addition to its primary long-term value for tracing the movements of continents and evaluating palaeogeography, palaeomagnetism is also used to unravel the history of reversals of the geomagnetic field polarity. Reversals have not occurred at regular intervals although there is a long-term trend for intervals of frequent reversal to become less frequent with time and move into long periods when there were no reversals (superchrons). Such intervals may last for tens of millions of years and when reversals recommence their frequency tends to increase again; this is a geomagnetic definition of a long term behavioral transition within the Earth's interior. The Cretaceous Normal "Superchron" (121–83 Ma) was the last long interval when reversals were absent. Subsequently the frequency of reversals has increased to a maximum about 10 Ma ago; since then the reversal rate has been generally declining. This history of magnetic reversals comprises the *geomagnetic polarity time scale* (GPTS), a chronology of periods of normal and reversed polarity. It forms the basis of magnetostratigraphy whereby the patterns of magnetic reversal are matched with the stratigraphic record of palaeomagnetism to date rocks and correlate them from place to place. The parallel investigation of the intensity of the geomagnetic field from rocks such as lava flows, which are rapidly cooled and magnetized, provides the essential data for monitoring the influence of secular variation and

investigating the behavior of the geodynamo. A further application of palaeomagnetism is the study of the anisotropy (fabric) of both the remanent magnetism and the magnetic susceptibility. This has applications to processes of sedimentation, the resolution of ancient tectonic stress fields, to fluid-migration and to economic mineral precipitation; a comprehensive guide to methods and applications can be found in Martin-Hernandez et al. (2004).

In common with all-natural materials, rocks possess a weak *diamagnetism* in applied magnetic fields as the electron spins align with, and oppose, an applied field. Minerals containing transition elements, the most important being iron and manganese, also possess a stronger *paramagnetism* as unbalanced electron orbits align with, and reinforce, the field. However, these effects are transient and only survive as long as the applied field is present. Although important to the interpretation of the ambient magnetic fields and of significance to ground surveys, they are not relevant to palaeomagnetism. Instead this relies on a memory of the magnetic field aligned with the ambient magnetic field at the time of rock formation, or at some later time period with an acquisition age determined from the geological history of the rock. In igneous and metamorphic rocks, this magnetic memory resides in grains with ferromagnetic properties which are usually iron-titanium oxides (titanomagnetites) comprising a few percent of the total rock volume. Although the intensity of the Earth's magnetic field is relatively weak (~ 0.5 Tesla), as these rocks cool through the Curie point they are capable of acquiring a strong and stable magnetism from this field. At high temperatures, the ferromagnetic minerals only have a transient weak diamagnetism and paramagnetism in the ambient field, but they acquire a permanent magnetization, *ferromagnetism*, as they cool through a critical temperature called the *Curie point* (generally $< 680^\circ\text{C}$). This is much lower than the temperatures at which many igneous rocks start to crystallize ($\sim 1200^\circ\text{C}$) and is lower than the higher grades of metamorphism (typically up to $\sim 800^\circ\text{C}$). If an igneous rock such as a dyke or lava flow cools rapidly at, or near to, the surface it will cool rapidly to this temperature over period of only days or weeks. It will then record a field direction which is instantaneous in geological terms; this becomes a *geomagnetic field direction* and part of the secular variation record rather than a long-term average of the field representative of the Earth's rotation axis. In contrast igneous rocks which cool slowly deep within the Earth's crust will integrate a record of the magnetic field over long periods of time; they may even record reversals of the geomagnetic field and yield a true *palaeomagnetic pole*.

Since rocks contain magnetic grains with a wide diversity of sizes and magnetic domain properties, their magnetizations are acquired continuously over a broad range of temperature below the Curie Point. This trapping of remanence from the Curie

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 1 A blocking temperature spectrum of Thermal Remanent Magnetization (TRM) showing the progressive fraction reduction of an initial magnetization M_0 . Each segment of the TRM is referred to as a

Partial Thermal Remanence (PTRM) and these segments obey a Law of Additivity: $TRM = PTRM(550-500^\circ) + PTRM(500-450^\circ) + PTRM(450-400^\circ) + \dots$

point down to ambient temperatures defines a blocking temperature spectrum (Fig. 1). In igneous rocks, the total spectrum is a *Thermal Remanent Magnetization (TRM)*. This can be considered to be the cumulative sum of *Partial Thermal Remanences (PTRMs)* obeying a Law of Additivity: the remanence fraction acquired over any particular interval is discrete and independent of the fraction acquired over any other interval (Fig. 1).

Many sedimentary rocks include grains of ferromagnetic minerals derived from the erosion of older rocks. When these grains are deposited they can be geomagnetically aligned if the influence of the Earth's magnetic field is stronger than gravitational and hydraulic forces. This is a *Depositional Remanent Magnetism (DRM)*. Usually sediments undergo a protracted history of compaction and cementing (lithification) and sometimes chemical alteration (diagenesis) and may well also be disturbed by the burrowing of organisms (bioturbation). As these processes operate, the ferromagnetic grains usually have the opportunity to become more precisely aligned into the geomagnetic field to give the rock a *Post-Depositional Remanent Magnetism (PDRM)* and define a true palaeomagnetic pole. Chemical changes resulting in the precipitation of new ferromagnetic minerals produce a *Chemical Remanent Magnetism (CRM)* which may also yield a magnetization integrated over a long period of time. In sedimentary rocks such as limestone ferromagnetic grains may be formed directly by diagenetic processes or they may incorporate magnetite grains precipitated by magnetotactic bacteria. Although these secondary processes are often still poorly understood, they operate over long time periods. They therefore always tend to integrate the geomagnetic field to provide information which is of palaeomagnetic, rather than of short-term geomagnetic, significance.

Palaeomagnetism is a time relaxation phenomenon so that all-natural magnetizations decay with time and relax into the field prevailing at the present day. Nevertheless, this relaxation time is very long, and longer than the age of the Earth for many small ferromagnetic grains. It is the very great length of time required for these natural magnetizations to decay which means that a record of permanent magnetism is still preserved, even within the oldest rocks on Earth. Nevertheless, it also means that if a rock is metamorphosed at an elevated temperature below the Curie point and this temperature is sustained for many millions of years, it is capable of being totally remagnetized. It will then acquire a new magnetism dating to the time of metamorphism.

In the late 1950s, it was also recognized that the rocks commonly acquire secondary magnetizations by a range of processes that include not only the influence of later temperature elevation, but also chemical change. The total magnetism in a rock, referred to as the *Natural Remanent Magnetization (NRM)*, is then the vector resultant of the primary magnetization acquired when the rock was formed and the secondary magnetization (which may include several components) acquired during subsequent geological times, and even imparted during coring and sampling. The chief goal of palaeomagnetic investigations is therefore to isolate the various components of remanence and ascribe an origin, age, and reliability to them. The resolved directions from each component may then be used to compute geomagnetic (short-term) or palaeomagnetic (long-term) pole positions. The following sections summarize the laboratory procedures and techniques of analysis employed in palaeomagnetism to achieve these goals.

Techniques of Sampling, Measurement and Analysis

Field Sampling

Palaeomagnetic sampling procedures follow a hierarchical approach in order to average the influence of secular variation and compensate for other inaccuracies such as the limitations of sample orientation. Sampling strategies are also adapted to the time scale of the scientific objective. Typically, oriented samples are collected from a number of different localities termed *sites*, each of which can be considered to represent a single time-instant record of the geomagnetic field. A number of such sites will be sampled within a single rock formation. The rock formation may comprise, for example, a suite of lava flows recording a volcanic episode, an igneous intrusion, or a succession of sedimentary beds. The sites clearly need to be *in situ*, cover a significant regional area, have tectonic histories which can be resolved, and collectively comprise a representative distribution through the time interval represented by the rock formation. This will ensure that although units such as lavas may record an instantaneous record of the field, the time interval covered by the survey is adequate ($\sim 10^5$ – 10^6 years) to average the effects of secular variation and any longer-term excursions of the geomagnetic field. It then derives a time-averaged assessment of the palaeomagnetic field direction. Each site will constitute a number of separately oriented samples (N) to compensate for orientation and instrumental errors and for possible failures to completely separate magnetic components during laboratory treatment. Sample orientation procedures typically have an uncertainty of $\sim 3^\circ$ but precision is gained in proportion to $N^{1/2}$ where N is the number of samples; thus, to improve orientation precision from 3° to 1° , nine or ten individually oriented samples would be required. In the case of magnetostratigraphy, where determination of the polarity of a rock level is the major objective, a minimum of three samples will determine the polarity unambiguously.

The samples are normally taken as oriented cores drilled in situ using portable hand-held drills which have been commercially available since the 1970s (Fig. 2), or may be extracted in the laboratory by drilling oriented block samples; the former method is preferred both because initial accuracy is higher and because accuracy is lost when block samples are reoriented for laboratory drilling. There are several orientation schemes currently in use, but each one employs an orientation device designed to provide an *in situ* geographic orientation using magnetic and Sun compasses (Fig. 2). Since the magnetism of the rock outcrop can influence the reading of a magnetic compass, Sun compass observations are preferred and use the direction of the shadow, together with a record of the time and sampling location; the azimuth is determined with the aid of the Astronomical Almanac or a simple algorithm. A new orientation device developed by

C. Constable and F. Vernon at the Scripps Institution of Oceanography (Lawrence et al. 2009) uses the Global Positioning System (GPS) and laser technology to produce similar accuracies to the Sun compass, although its application requires at least an additional half hour. Nonetheless, achieving sun-compass accuracy is a major breakthrough for palaeomagnetic field procedures in regions where siting of the Sun may not be possible. The palaeomagnetic specimens recovered for laboratory analysis are typically cylinders ~ 1 -inch-long and 1 inch in diameter (Fig. 2).

A palaeomagnetic field sample should be integrated with geological evidence so that it incorporates widely separated localities linked to defined rock formations for which the tectonic setting is properly understood; this will enable any effects of tectonic deformation on the recovered directions of magnetization to be accounted for. The survey will also need to accommodate effects of regional or local heating by metamorphism or igneous activity, and also the possible influence of chemical alteration, for example, by hydrothermal activity. It is also best to avoid elevated exposed locations because these tend to focus lightning. Lightning is a strong line current and the associated magnetic fields can induce a large *Isothermal Remanent Magnetization* (IRM) which is capable of completely replacing an ancient remanent magnetism in the rock.

There are a number of palaeomagnetic field tests which can be applied to help constrain the age of the magnetization in a rock formation. The *fold test* compares the directions of magnetization derived from limbs of fold with contrasting attitudes before and after adjusting for the tilt of the beds (Fig. 3); an improved grouping after adjustment indicates that the magnetization was acquired before the folding episode occurred. Sometimes the optimum grouping of directions is attained at an intermediate stage of untilting; this indicates that the magnetization was acquired during the tectonic event responsible for the folding. The *contact test* evaluates the remagnetization influence on the country rocks bordering an igneous intrusion. If the thermal influence of the intrusion diminishes with distance, it is likely that the intrusion has a primary remanence dating from initial cooling; if however, the magnetization across a widespread bordering region in the country rock is the same as the intrusion it will be apparent that the whole region, including the intrusion, has been subject to blanket overprinting. The *conglomerate test* compares the directions of magnetization in a number of pebbles in a boulder bed, preferably when these pebbles can be linked to a source in an underlying bed (Fig. 3). If the directions are random it demonstrates that pebble bed has not been remagnetized since formation; the magnetization in the bed from which the pebbles were derived is then also likely to be primary, although this would need to be independently established. If the directions of magnetization in the pebbles are uniformly directed, it is apparent that a later remagnetization event has influenced the pebble bed as well

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 2 Collecting and orienting rock samples for palaeomagnetic study. The cores are drilled (a) with a portable motorized coring machine. (b) An orienting tool is inserted around the core to determine

the inclination and the azimuth by Sun and magnetic compasses. (c) The core is extracted and coded. (d) A line on the core is used to fix the extracted core with respect to the orientation readings using a directed line on the top or the bottom

Paleomagnetism, Measurement Techniques and Instrumentation,

Fig. 3 Schematic cross section of ground showing a fold and conglomerate layer with magnetic components (black arrows) illustrating the concepts behind the fold and conglomerate tests used in palaeomagnetism

as the source formation beneath. The *reversal test* compares directions of opposite polarity to evaluate whether they are statistically antiparallel and therefore likely to be the record of a reversing dipolar field. Each of these tests can be placed on a sound statistical basis using methods described in textbooks such as Tauxe (1998).

Measurement and Treatment

The Natural Remanent Magnetization of a rock sample is the vector sum of the remanent magnetic moments of all the

magnetized particles contained within it. These particles are likely to have a wide range of sizes and magnetic domain structures, so the record of primary to secondary magnetization (or even no preserved remanent magnetism at all) will vary greatly. Magnetometers measure the magnetization of rock samples in three mutually perpendicular directions (X, Y, and Z) and the values are compounded to yield the magnitude and direction of the resultant vector. Using the field orientation parameters for the sample (usually as noted above, in the form of short cylindrical cores), the data from the specimen

coordinate system can be transformed into geographic coordinates and displayed graphically on a stereonet. The geographic vector can be considered in terms of declination (D), inclination (I), and magnitude (M); M does not change during the transformation of coordinate systems.

The observed NRM of rocks may consist of any combination of primary and secondary components and it is essential to separate these to unravel the magnetic history of the rock. Since any sample will comprise multiple grain domain properties, this separation can be achieved by partial demagnetization referred to as “cleaning.” The methods rely on the observation that magnetic components of different ages and modes of acquisition usually have contrasting thermal and magnetic blocking temperature spectra. Alternating field and thermal demagnetization techniques are a routine part of palaeomagnetic investigations and depend on the relationship of relaxation time to coercivity and temperature to subtract (demagnetize) lower coercivity or blocking temperature components. Alternating field (AF) demagnetization selectively removes components with the short relaxation times that typically have lower coercivities. Thermal demagnetization is also applied progressively, this time employing the observation that grains with the lower unblocking temperatures also tend to have the lower relaxation times, τ , and are therefore more likely to carry a later secondary magnetization.

All ferromagnetic grains are subject to a number of competing internal molecular-level forces (see, for example, Butler 1992; Tauxe 1998) and larger grains tend to subdivide into zones of homogeneous magnetization in order to minimize the total magnetic energy. These *domains* are separated by narrow domain walls, typically up to 100 atoms thick, where the magnetic dipoles are canted around from one orientation to another. In magnetite (Fe_3O_4) bearing rocks, the secondary NRM tends to be carried mostly by multi-domain (MD) grains with lower relaxation times, while the primary characteristic remanence (ChRM) tends to be retained by single domain (SD) or pseudo-single domain (PSD) grains; although these latter grains have sizes larger than SD, SD properties are fixed by shape or defect properties which enables them to retain a comparable remanence to SD. MD grains have coercivities predominantly <20 mT, whereas SD and PSD grains typically have a broad range of higher coercivities. AF demagnetization can therefore selectively remove secondary NRM and leave the primary magnetization largely unaffected. Rocks containing the less common ferromagnetic minerals pyrrhotite (Fe_{1-x}S) and maghemite ($\gamma\text{Fe}_2\text{O}_3$) have properties which are closely comparable to magnetite, whereas hematite ($\alpha\text{Fe}_2\text{O}_3$), which tends to be the commonest ferromagnetic constituent in sedimentary rocks deposited in an oxygenated environment, has much higher coercivity and cannot be effectively subtracted by the fields achieved by most AF demagnetization systems. However, since hematite has a higher Curie point ($\sim 670^\circ\text{C}$) than

the other common ferromagnetic minerals, it can usually be isolated by demagnetization to temperatures above $\sim 580^\circ\text{C}$. Because hematite is also found as an oxidation product of magnetite in igneous, metamorphic, and sometimes in sedimentary rocks, primary magnetization residing in magnetite may first be unblocked below a secondary magnetization residing in hematite during progressive thermal treatment. The nature of the magnetizations resolved by palaeomagnetism is determined by rock magnetic studies. These usually involve the application of a controlled laboratory magnetism or temperature. The methods used in rock magnetic investigations are described in all the standard textbook on palaeomagnetism.

Since AF demagnetization is unable to completely subtract the magnetism in a rock because the applied alternating fields required to do this are simply unattainable in the laboratory, and would in any case present their own problems, only thermal demagnetization is capable of fully subtracting magnetization if continued beyond the Curie point. Nevertheless, while bulk AF treatment of rock collections is now amenable to automation and can permit rapid data acquisition, thermal demagnetization requires stepwise heating and cooling in a zero magnetic field, so that all magnetization blocked below the assigned temperature is then unblocked and removed. Inevitably this is a longer procedure and only amenable to limited automation. In both cases, the successive measurements of magnetization should be conducted in a field-free space so that magnetization cannot readily be imparted from the ambient field before the treated samples have been measured.

Analysis

A stereographic plot of magnetization directions at each stage of demagnetization treatment, although generally used in older studies (see Collinson 1983 for details of plotting), is not a satisfactory way of resolving the components of remanence because these directions will likely record the resultant of two or more components. Instead the results of progressive treatment are compiled as vectors in two-dimensional space by projecting the magnetization vector (i.e., with both magnitude, M, and direction resolved into D and I) onto two planes at right angles. These projections of the horizontal and vertical projection are combined together onto a single projection describing an orthogonal plot. They were first applied to a palaeomagnetic study by R.L. Wilson (1961); the display technique was formalized by Zijdeveld (1967) and has been in routine application ever since. The D, I, and M data of the progressive demagnetization experiments are most commonly resolved into north, east, and downward (or upward) components to yield a diagram like the one illustrated in Fig. 4 where it is common practice to denote projections onto the horizontal plane and vertical planes by solid and open symbols, respectively. The origin of the Cartesian coordinate

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 4

The orthogonal projection of demagnetization data during progressive demagnetization. When (a) there is no overlap between the blocking temperature/coercivity spectra of the sample, the lower and higher components are defined by discrete straight-line segments as they are unblocked by thermal demagnetization or subtracted by AF demagnetization. As the overlap of the spectra increases ((b) and (c)) the orthogonal projection becomes progressively more curved and linear segments are no longer observed when both spectra are being subtracted at the same time (c). Note that declinations can be read directly from the horizontal projection of the vector but a direct reading of inclination from the plot is not possible. (After Collinson 1983)

system is the point at which all magnetization has been subtracted; it is routinely reached with comprehensive thermal treatment, but will rarely be attained by AF demagnetization unless only very low coercivity MD grains are present in the sample.

A critical observation is that a linear trend of projected points defines the progressive removal of one component only (Fig. 4a). If this line migrates towards the origin of the projection, it demonstrates that only the high unblocking temperature or coercivity magnetization is left to be removed. The successive removal of the lower unblocking temperature or coercivity magnetizations, and the isolation of the highest unblocking temperature/coercivity component, can be achieved by the recognition of successive linear trajectories. The last component to be resolved is designated as the *Characteristic Remanent Magnetization* (ChRM) because it is usually the most interesting component for interpretive purposes and likely to be the earliest magnetization acquired by the rock, and often of primary origin; the secondary

components removed below this may be of interest for resolving the later history of the rock, especially if they can be linked to an event such as a thermal pulse or a diagenetic episode. The direction of any component represented by a straight-line segment on an orthogonal plot is resolved by extracting the component from the data above and below, and treating it as if it were a unique record.

The trajectories of vector projections depend upon the degrees of overlap of the coercivity or blocking temperature spectra (Fig. 4). When the spectra do not overlap, the vector diagram displays successive linear trajectories, each one recording the subtraction of a component. If overlap is only partial, straight line trajectories are still identified but intermediate points corresponding to the overlap display a curved trajectory (Fig. 4b). If there is complete overlap between the spectra, the vector component diagram does not possess linear segments (Fig. 4c), although the trajectories may sometimes be used to isolate the components if they define a great circle, a "circle of remagnetization." A single great circle on its own

provides insufficient information to estimate the ChRM direction, but if more than one circle is available from different specimens and these circles converge, then the convergence point, or its antiparallel equivalent, can yield an estimate of the ChRM. Halls (1979) reports a procedure for calculating the best fitting convergence point of several great circles. The majority of convincing palaeomagnetic results come from one and two component structures, although palaeomagnetic workers have now ventured into the study of rocks with varied histories comprising multicomponent NRMs, with combinations of AF and thermal demagnetization used to isolate complex remanence histories.

The procedure for separating and resolving the directions of individual components is known as *Principal Component Analysis* (PCA) and comprises a method for determining the direction of the lines or planes which best-fit the data described by the orthogonal projections (Kirschvink 1980); essentially a component segment is extracted from the orthogonal projection and isolated as though it is the only component present in the rock. An advantage of this method is that it compensates for errors due to signal to noise ratio, and provides a quantitative measure of the precision of the direction. The precision of the direction determined from the best-fit line is described in terms of a *Maximum Angular Deviation* (MAD), while MAD values $<12^\circ$ are usually considered acceptable, much higher degrees of precision should be aimed for, especially in youthful rock material.

Statistics

As with all experimental data, the directions resolved by PCA will be associated with a number of random errors arising from factors such as instrument noise, inaccuracies in sample orientation, imperfections in demagnetization, and secular variation of the recorded geomagnetic field. The net result of all these factors is a dispersion from which the researcher requires the best estimate of the mean direction. Determining a mean and confidence limit from any set of values by a statistical method is based on a probability density function. A function applicable to palaeomagnetic directions was developed by Fisher (1953) and provides a simple procedure for treating palaeomagnetic data. Fisher's analysis treats each accepted direction in the population as having a unit weight and represents it as a point on a sphere of unit radius. The dispersion of these points on the sphere is assumed to have a circular Gaussian distribution (Fig. 5) and the mean of the set of directions is calculated by vector addition: each unit vector is resolved into three orthogonal components in Cartesian coordinates. The components are summed to obtain the length of the resultant vector (R) and the mean direction (D and I). D and I define the direction of the best estimate of the mean, while R is used to assess confidence in the result.

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 5 The Fisher circular distribution derived from the Gaussian probability function. $P_{dA}(\theta)$ is the probability per unit angular area of finding a direction within an angular area, dA , centered at an angle θ from the true mean. Distributions are shown for values of the precision parameter κ , of 50, 10, and 5

Two simple parameters, k and α_{95} , are used to illustrate the quality of the calculated mean in palaeomagnetic studies. The probability of finding a direction at an angle (θ) from the calculated mean is expressed in terms of a probability function involving a precision parameter κ . Fisherian statistics use an approximation for κ defined by a parameter denoted by $k = (N - 1)/(N - R)$ where N is the number of directions and R is the length of the resultant vector. The α_{95} value in degrees defines the angular radius of the cone of confidence projected from the center of the unit sphere within which we have 95% confidence that the true direction actually lies. It is simply calculated from $\alpha_{95} = 140/(k \cdot N)^{1/2}$ and is comparable to the standard estimate error of the mean in Gaussian statistics; 5% of the observed directions are expected to fall outside of this circle. High reliability in palaeomagnetic analysis is therefore expressed by large k and small α_{95} . As with all statistical analysis, precision estimates are improved by increasing the sample population although in terms of experimental effort the increase becomes progressively less worthwhile for large values of N . Sample populations from a single unit such as a lava flow are generally considered satisfactory if N is 7 or more, whilst k values <10 are unsatisfactory.

Determination of Palaeomagnetic Poles

The resolved mean direction of magnetization is used directly in much analysis and interpretation – in regional small to

medium scale tectonic problems, for example. However, for larger scale analysis such as the determination of past global geometries and analysis of the geomagnetic field, it is necessary to convert it into an equivalent pole position. This also provides a meaningful way of comparing ChRM directions from rock formations of same age, but widely separated on the same continent or tectonic plate; for this purpose, a common reference system is necessary and is provided by the palaeomagnetic pole. The pole position is the position where the geomagnetic field axis responsible for the observed palaeomagnetic field direction meets the surface of the Earth. A model is required to perform this calculation. Since more than 90% of the present geomagnetic field can be explained in terms of an axial geocentric dipole source, this is the model normally used to calculate palaeomagnetic poles and the position is expressed in the present geographic longitude–latitude grid. For a palaeomagnetic field of inclination I , the ancient latitude (λ) of the site is given by the formula $\tan I = 2 \tan \lambda$. The equations required to calculate the position of the palaeomagnetic pole require the declination D and the coordinates of the sample locality in addition to the inclination; they are more complex but are provided in all palaeomagnetic text books (see for example, Tauxe 1998).

The geomagnetic pole calculated from a single geomagnetic field observation (from a single lava flow for example) yields a *Virtual Geomagnetic Pole* (VGP) and will include components of the nondipole field incorporating the secular variation. A palaeomagnetic pole is calculated by averaging a number of VGPs derived, for example, from several lava flows or levels through a sedimentary section; it is expected to have averaged nondipole field components and represent the Earth's rotation axis at the time that the ChRM was acquired by the rocks. The angular dispersion of the VGPs constituting the collection can be used to test whether this is effectively achieved by comparison with the dispersions recorded by secular variation during historic and recent geological times (McFadden et al. 1991). The expected angular dispersion is a function of latitude, although the comparison is presently of limited value because the comparative database is sparse in the southern hemisphere and temporal coverage is poor. Confidence limits for a palaeomagnetic pole are derived from α_{95} , the radius of the cone of 95% confidence about the mean direction. These translate into an oval of confidence within which we have 95% confidence that the pole actually lies. The maximum and minimum radii of this oval are given by $dp = 2 \alpha_{95} (1/(1 + 3\cos^2 I))$ and $dm = \alpha_{95} (\sin p/\cos I)$ where p is the magnetic colatitude or the great-circle distance from the sampling location to the pole.

Instrumentation

The intensity of magnetization of rocks can vary by several orders of magnitude. Young basic lavas are often so strong

that their magnetizations can often be approximately determined with a hand compass. At the other extreme rocks such as pure limestones are so weak that it is only the presence of sparse magnetotactic bacteria that may give them a very weak remanence; this is only detectable with sophisticated cryogenic magnetometers developed in recent decades. The early studies in the 1950s and 1960s were inevitably concentrated on the more strongly magnetized igneous rocks and red sediments. The pioneering instrument for this was the parastatic magnetometer developed by Blackett (1952) which employed the deflection of a suspended unstable astatic magnet system. Samples were brought into proximity to disturb this system; they would be individually measured in three orthogonal directions, each in antiparallel configurations yielding six measurements in all, and used to calculate a resultant direction. Each measurement required a time integration for the deflection to stabilize and was inevitably relatively slow with the instrument often subject to local vibrations and fluctuations in the ambient field. Vibration and magnetic noise issues were overcome and measurement speed enhanced with the development of spinner magnetometers. These were amenable to successive improvements; with the speed of rotation of the sample near the detecting system enhanced, sensitivity could be improved and this expanded the range of rock types available for investigation, notably into a broader range of weakly magnetized sediments. High speed spinner magnetometers can achieve sensitivities approaching superconducting magnetometers but they are not amenable to the treatment of more friable rocks. Superconducting quantum interference magnetometers (SQUIDs) are now most widely used to evaluate remanence in more weakly magnetized rock types.

Spinner Magnetometers

Spinner magnetometers operate in accordance with Faraday's law whereby the magnetic field averaged along an axis of a spinning sample generates an electric current in a detection coil, or sensor, to produce an electromotive force (EMF). The sample will typically be spun within, or adjacent to, a fluxgate detecting system. The amplitude of the output EMF is proportional to the component of magnetic moment perpendicular to the rotation axis ($P_{\perp}$), and the phase of the voltage is utilized to relate the direction of the measured component to a reference direction in the sample. The sample is rotated successively about three axes to obtain average values of the NRM components and reduce the effect of inhomogeneity to $\sim 2^\circ$ in direction and $\sim \pm 5\%$ in intensity. Measurement of weak magnetizations has been achieved by increasing the rotation speed and careful design of the pick-up coil systems. Since electric motors operating at a frequency of ~ 100 Hz are required for rotating the samples, a challenge to the design has been the requirement to shield this unavoidable source of

electromagnetic noise from the measuring assembly. The problem can be reduced by using an air turbine and in modern magnetometers, the frequencies used are in the range 5–80 Hz with signal discrimination circuits employed to reduce the effects of noise.

The usual procedure for NRM measurement is to spin each sample in six mutually orthogonal orientations so that any two of X, Y, and Z are in turn perpendicular to the spin axis. Since two orthogonal components of magnetization are obtained from each spin, the orientations are chosen to provide four determinations each of X, Y, and Z, usually two of each sign for each component. This procedure tends to average out any random noise on the signals, the effects of inhomogeneity of NRM, and any remanent magnetism in the part of the sample holder permanently attached to the shaft. The six sample orientations used should ideally satisfy the following: (a) provide two values each of +X, +Y, and +Z, (b) distribute the displaced dipole caused by inhomogeneity of the NRM as uniformly as possible, (c) average the possible error arising from imperfect calibration of the NRM direction of the magnetometer, and (d) measure each NRM component in each “channel” of the magnetometer (i.e., the sample will be placed in the holder with X, Y, and Z in turn parallel and perpendicular to the reference direction).

Some commercial spinner magnetometers (Fig. 6b) can now achieve sensitivities close to those attainable with SQUID magnetometers and supplied with software for online analysis of the data, although due to their need to run at high speed, they are unsuitable for friable or poorly shaped samples. The dual speed JR-6 (AGICO Ltd; Czech) series spinner magnetometers have sensitivities of $\sim 2.4 \times 10^{-6}$ A/m and can measure up to 12,500 A/m. A much cheaper compact spinner

magnetometer, the “Minispin” (MOLSPIN Ltd; UK), is no longer available but its modified version “Portable Spinner Magnetometer” suitable for the routine measurement of more strongly magnetized samples came onto the market recently.

Cryogenic Magnetometers

Developments in cryogenic technology have allowed two important advances in palaeomagnetic research. Firstly, they have permitted an increase in sensitivity by one to three orders of magnitude which, combined with rapidity of measurement, allows an unlimited range of rock types to be studied. Secondly, they have allowed magnetism in a sample to be measured by a single insertion into the sensing coils because only one axis of the sample needs to be presented to the magnetometer. Magnetic and thermal cleaning can then potentially be automated with the measuring procedure. Cryogenic magnetometers use the properties of a superconducting ring made of a metal with perfect diamagnetism which causes the expulsion of all magnetic flux from the ring below a certain temperature. When an external field is applied in the superconducting state, all flux is expelled from the interior of the metal but not from the hole within the ring; as a result, induced currents flow in one direction on the outer face of the ring and in the opposite direction on the inner face. If the applied field is removed, the currents on the outside of the ring disappear, while the current on the inside face persists to maintain a field within the ring.

The ability of the ring to trap and maintain magnetic fields to better than one part in 10^9 can be used in magnetometry to trap a zero field within the loop and use this volume for

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 6 Instrumentation in a typical palaeomagnetic laboratory. Measurements and demagnetization procedures take place within large sets of Rubens coils designed to continuously nullify the ambient geomagnetic field. In (a) two thermal demagnetizers are stacked on the right; these are designed for the treatment of trays of multiple cores to specified

temperatures for programmed time intervals. On the left the operator is using one of two interfaced spinner magnetometers for measurement of relatively strongly magnetized rock samples. (b) Two magnetometers used for the measurement of weakly magnetized rock samples comprise a FIT hydrogen SQUID magnetometer on the left and a JR6 high speed spinner magnetometer on the right

measurement. These magnetometers are operated at the superconducting-resistive boundary; the ring current is quantized so any flux entering the ring at this transition state is also quantized and measured in terms of a feed-back current. The magnetometer is surrounded by an insulating evacuated space cooled by liquid helium or nitrogen, while pick-up coils connected to SQUID detectors are employed to measure the NRM along one axis, or simultaneously along two or three mutually perpendicular axes. Mumetal shields are employed to blanket external field variations and some automated systems allow complete demagnetization within this field-free environment. Cryogenic magnetometers are faster and typically more sensitive than spinner magnetometers but cost much more to purchase and operate; the liquid nitrogen represents an ongoing cost, and while helium can achieve lower temperatures, it is more expensive and less commonly used these days. For further details, the reader is referred to Collinson (1983) and Tauxe (1998).

Alternating Field Demagnetizers

The AF demagnetization procedure applies an oscillating field to the specimen in a nullified magnetic field environment. The equipment comprises a coil, a capacitor bank for tuning the coil, a power supply, and current reduction mechanism; a coil system or magnetic shield aims to minimize the ambient field over the sample and sample tumbler. The rock specimen is rotated within the center of the coil in a tumbling system incorporating simultaneous rotation about horizontal and vertical axes. The ratio of the two tumbling rates is designed to expose as many configurations of the sample as possible to the applied field acting along the axis. The applied current is then smoothly reduced to zero as the specimen continues to rotate. It is essential to ensure that the geomagnetic field within the demagnetizer is completely cancelled or the specimen may acquire an *Anhyseretic Remanent*

Magnetization (ARM), and an alternating field with a very pure waveform is essential for the best results to avoid rotational and gyro magnetic effects. Most modern AF demagnetizers are designed to achieve initial fields in excess of 100 mT.

The theory of AF demagnetization is explained by Butler (1992). The waveform of the applied alternate magnetic field is a sinusoid with linear decrease in magnitude with time (Fig. 7). The expanded figure (b) emphasizes the smooth decrease required. All the grain moments with coercivities below the peak AF will track the field. These entrained moments will become stranded however, as the peak field drops below the coercivities of individual magnetic domains. The directions of stranding will be effectively random if the tumbler has been appropriately designed to present as many configurations as possible of the sample to the declining applied field. By progressively increasing the applied field, the domains of successively higher coercive force are randomized or subtracted from the total measured remanence. The coercive spectra of the sample can then be resolved up to the maximum field of demagnetization and contributions of successive components to the NRM resolved by application of orthogonal projections and PCA. As noted above, AF demagnetization is unable to fully subtract the NRM and is ineffectual with hematite-bearing rocks due to their high coercivity.

Commercially available alternating field demagnetizers include the D-2000-DTECH AF demagnetizer and the AGICO-LDA5 AF demagnetizer systems. Both are in wide use and can demagnetize samples up to a peak field of 200 mT with multiple field decay rates using both manual and tumbling facilities. The D-2000 can demagnetize five to six samples simultaneously at any chosen peak field, and both units can be used for rock magnetic experiments by imparting complete or partial anhysteretic magnetizations (ARM and PARM) using a controlled direct current applied continuously across the AF demagnetizer coil.

Paleomagnetism, Measurement Techniques and Instrumentation, Fig. 7

(a) The generalized wave form of the magnetic field used during AF demagnetization and (b) expanded version of a small portion of AF demagnetization between two successive peaks. (After Butler 1992)

Thermal Demagnetization

Thermal demagnetization is achieved by demagnetizers that serve the purpose of both demagnetizing the NRM in palaeomagnetic specimens and applying a partial thermal remanent magnetization (pTRM); the latter procedure is used for investigating the record of the ancient intensity (palaeointensity) preserved in suitable rocks. If the temperature of the sample is raised until the relaxation time of some fraction of the particles carrying NRM has been reduced to a few minutes or less, the NRM of these particles will be unblocked. Their contribution to the NRM of the rock will be lost if they are cooled to the ambient temperature in a zero field. In this way, the contribution of lower stability grains to the NRM can be randomized. Alternatively, if a DC field is applied during cooling, the grains whose unblocking temperatures have been exceeded will be realigned into the new applied field direction; they will then have acquired a pTRM. If the rock sample is subjected to successively higher temperature treatments, the lower blocking temperature components will be progressively removed. The components contributing to the NRM are then progressively subtracted and can be resolved by projecting the successive magnetizations onto an orthogonal projection and applying PCA.

Thermal demagnetizers comprise a magnetic shielding system to exclude the ambient field, a furnace, a thermocouple, and temperature control unit. A prime concern is the neutralization of the external magnetic field. To balance the times for measurement against the times taken for heating and cooling, the oven needs to be of sufficient size to hold a reasonable number of samples (10–50) and apply a uniform temperature through them ($<\pm 10^\circ\text{C}$ at 600°C). It is required to be capable of heating samples to a temperature in excess of the highest Curie points of the ferromagnetic minerals ($\sim 700^\circ\text{C}$) over a modest time (~ 1 h). The heating coil is wound onto the curved surface of a silica tube forming the inside wall of the furnace in a noninductive way to reduce stray magnetic fields. The maximum available voltage will normally be that of the electrical mains. The maximum current is dictated by the temperature controller using a variable transformer determining the resistance of the furnace winding. Between 20°C and 700°C the resistance of the winding increases by 5–10%. If the resistance determined from the available voltage and current is the cold resistance, the current (and heating rate) will decrease at high temperatures; if it is the hot resistance then the cold current will be slightly above that calculated. The wire diameter is controlled by the size of the furnace, while the number of turns and their minimum separation is set by the requirement for adequate insulation between them; as separation is increased, the uniformity of temperature deteriorates.

Although large furnaces are useful for dealing with many samples at once, their thermal inertia is considerable and may cause problems with temperature control. A suitable

thermocouple material is Pt/13%Pt-Rh, with an output of ~ 6.7 mV at 700°C . The thermocouple tip may be covered with a standard rock sample with an axial hole drilled in the center. The controller then senses the furnace temperature via a thermocouple placed close to the furnace winding. By ensuring that the thermal inertia of rock and thermocouple are similar, the rock samples should be uniformly heated throughout the indicated temperature. Several commercial temperature controllers are available for automatically raising and holding the furnace temperature to a preselected value.

Some furnaces are designed so that it is possible to conduct heating/cooling cycles in an inert atmosphere or in a vacuum to minimize oxidation. Although thermal demagnetizers are in principle, capable of completely removing the NRM in a rock and thereby recovering the entire component structure in a way that is not possible with AF demagnetization, this is seldom fully achievable in practice. The limitations are the difficulty of completely cancelling the ambient magnetic field without excessive shielding and the possibility of chemical alteration during the successive heating and cooling cycles. To surmount the latter problem, microwave systems have been developed to provide an alternative source of heating. These have been successfully applied to palaeointensity studies in a small number of laboratories (Walton et al. 1992), but have not yet been produced with a capability of routine demagnetization of NRMs.

The MMTD Thermal demagnetizer (Magnetic Measurements; UK) and the TSD1 Thermal Specimen Demagnetizer (Schonstedt; USA) are the two popular Commercial units in common use today. Both achieve a very low magnetic field environment (< 10 nT) and can attain furnace temperatures up to 800°C . The new generation MMTD demagnetizer is capable of handling a large number (~ 80) of samples. In the TSD1, both heating and cooling chambers are separately arranged in a coaxial manner. Although only handling about ten samples in a batch, cooling of one set can accompany heating of the next batch and achieve relatively rapid processing. In the MMTD successive heating and cooling of a single but large batch takes place in the same chamber.

A Perspective on Seventy Years of Palaeomagnetism

Seven decades have now passed since rock samples were first introduced to sensitive suspended magnet systems to evaluate their magnetism. Following pioneer work in Japan and the UK, the 1960s saw a rapid extension of studies to the USA, Australia, Africa (former Rhodesia), Holland, and the former USSR (extensive results but only incompletely tested and reported). The intervening time has seen palaeomagnetic laboratories established in most countries of the world, specifically to address the palaeomagnetic record in their geological

successions. Great technological improvements in the equipment used for these studies have accompanied developments in the field of electronics. The prime emphasis has been on expanding the numbers of samples that can be measured and speeding up the treatment by improved AF and Thermal Demagnetizers. While the original equipment was usually built in-house, an impressive range of commercially available equipment is now able to cater for the expanded world market. It is now possible to conveniently evaluate component structures of magnetizations in more detail than was possible in times past. Although the conclusions may not be substantially altered, this provides a strong motivation for revisiting earlier studies where component separation may well have been incomplete.

We illustrate modern developments with two examples. Wack and Gilder (2012) describe an automated system for palaeomagnetic investigations. Based on a migrating SushiBar system, up to 99 samples can be rapidly loaded and unloaded, and AF demagnetized. The progressive treatment system also enables the researcher to examine magnetic properties using an applied anhysteretic remanent magnetization (ARM) through any coercivity window up to the peak field. This paper also compares the properties of the SQUID systems developed since 1984. As the emphasis on palaeomagnetic studies has diminished somewhat in recent years, the studies of palaeointensity have expanded as we seek to understand more about the long-term behavior of the geodynamo. A recent development is reported by Fukuma and Kono (2016) who describe an automated system which couples a magnetometer with an electric furnace controlled by software that ensures an efficient and identical double heating of samples. This is required by the Thellier method (1959) which likely remains the most reliable method for determining ancient intensities of the magnetic field.

Summary

A record of the past magnetic field, known as magnetic remanence, is preserved by ferromagnetic mineral grains in rocks and other natural materials. These minerals are mostly oxides of iron (magnetite, hematite, maghemite) and the sulfide mineral pyrrhotite. Although they usually comprise no more than a few percent of the total rock volume, they provide key information in the disciplines of geology and geophysics and have further applications in the environmental sciences and archaeology. The material for study is collected in the form of small oriented samples in sufficient numbers for robust statistical analysis and in distributed amounts to be representative of a sample of a fossil magnetic field. The record can apply to short periods of time in the study of secular variation, short term geomagnetic field fluctuations, and the record in archaeological samples such as thrown

bricks, heated pottery, and kiln material. Alternatively, it can apply to long periods of time when applied to determining pole positions for rock formations spanning millions of years to evaluate past continental motions, or to establish polarity and link it to the Geomagnetic Polarity Time Scale. The magnetizations are measured using magnetometers designed to determine natural magnetizations ranging from strong to very weak. The instruments used for determining these magnetizations nowadays are either spinner magnetometers which measure the current induced in a detector system as the sample is spun near to a coil, or SQUID magnetometers based on cryogenic technology. The latter systems are more rapid and versatile but are expensive to operate and beyond the scope of many laboratories to afford.

The magnetizations in most materials are composite effects comprising the vector sum of a primary magnetization often imparted when the rock was formed, and secondary magnetizations acquired during later events that may have influenced the rock. These component magnetizations are separated and resolved by demagnetization procedures that progressively subtract the magnetization resolved either in terms of the coercivity spectrum of the magnetization (AF demagnetization) or the blocking temperature spectrum (thermal demagnetization). The magnetizations are resolved by projecting the successive values of the magnetization vector during this progressive treatment onto a two-dimensional orthogonal plot and identifying the constituent components from their contributions to the coercivity/blocking temperature spectra. The populations of magnetic directions resolved from a palaeomagnetic study are statistically analyzed using a system of (Fisherian) statistics assuming that each direction is of equal importance, and that the population can be represented in terms of a circular Gaussian distribution. Two simple parameters comprising a precision parameter, k , and a cone of 95% confidence α_{95} are used to express the quality of the result. The mean direction is normally converted into an equivalent geomagnetic or palaeomagnetic pole by assuming that the source of the field direction resolved at the surface of the Earth originates in a geocentric dipole source within the Earth's core. In the long-term application spanning at least thousands of years, this dipole may also be assumed to be axial and constrained to the rotation axis of the Earth.

Paleomagnetism, Polar Wander

Jean Besse¹, Vincent Courtillot² and Marianne Greff²

¹Laboratoire de Paléomagnétisme, Institut de Physique du Globe de Paris, Paris, France

²Institut de Physique du Globe de Paris, Paris, France

Definition and Introduction

For more than two centuries, geoscientists have suggested, based on geological field observations (reconstruction of paleoclimate belts based on fossils or certain rock types),

that the past Earth's equator (and Equatorial conditions) must have at some time been located far from its present position. In the early 1950s, paleomagnetists such as Runcorn (1956) provided quantitative evidence that the instantaneous geographic or rotation pole had moved with respect to certain continents. The paths followed by the poles in the geological past were termed “apparent” polar wander paths (APWPs), because it was not clear whether it was the pole or the continent that had moved. Since then, we have learned that oceanic and continental plates have moved with respect to each other and that a significant part of APW was actually due to these relative motions. A remaining fraction in polar wander, which would be a characteristic of “Earth as a whole” and which would not be accounted for by plate tectonics, is called “true” polar wander (TPW). True polar wander refers thus to the large-scale motions of the Earth's rotation axis through geological time. External forces driving shorter-term changes such as precession are not taken into account here.

True polar wander could result from centrifugal forces acting on mass anomalies distributed on or inside the Earth: excess mass, for instance, will lead to slow deformation of the Earth and change its rotation axis, causing the mass to move towards the equator without being displaced with respect to the solid Earth. The problem is to define precisely in a deformable Earth which part wanders with respect to which reference frame. What is defined (e.g., Steinberger and O'Connell 2002) is the axis of rotation of a reference frame (RF) relative to an inertial frame of reference (i.e., determined by the angular momentum vector of Earth). The reference frame can be selected as the one that has zero net rotation when motions are integrated over the entire mantle, called the “mean mantle” reference frame. Or one can also define a “mean lithosphere” frame, in which the lithospheric plates have no net rotation. These frames in general do not coincide (Ricard et al. 1991; O'Connell et al. 1991). The “mean mantle” frame can be computed in numerical simulations in which the density distribution is given over the entire mantle. However, if one attempts to constrain it with actual paleomagnetic observations, one has to assume that the “mean mantle” frame is identical to some frame based on observations: the “hotspot reference frame” will most often be the one involved. Steinberger and O'Connell (2000) show that the approximation (discussed later in this paper) is quite good even if hotspots move in the convecting mantle.

The crust and mantle actually deform actively at the typical velocities of plate tectonics (~10–100 mm/year). Thus, polar wander involves (relative) motions of the rotation axis with respect to the Earth's mantle.

Goldreich and Toomre (1969) hypothesized that large-scale polar wandering and continental drift shared a common explanation through mantle convection and the resulting redistribution of masses within the mantle. Goldreich and Toomre (1969) started their analysis of the motions of the

rotation axis of a quasi-rigid Earth with the classical figure, where a colony of beetles (the continents or other mass anomalies) moves slowly at the surface of a rigid rotating sphere (Fig. 1). They simulated very large polar wander, with particularly intense and rapid swings.

The physics of TPW is explained among others by Ricard et al. (1993a): TPW is seen as the result of conservation of angular momentum of a rotating, deformable body, whose inertia tensor slowly changes with time. The reasons for the changes are mass redistributions linked to mantle convection. In simple terms, the inertia tensor component that affects polar wander is related to subducting slabs, upwelling plumes, and more generally thermal and chemical mass heterogeneities resulting from a long history of mantle convection. With estimates of degree 2 components of the geopotential derived from satellite data, it can be shown that the non-hydrostatic part of the Earth's inertia ellipsoid is triaxial, the present rotation axis coinciding with the largest of the non-hydrostatic moments of inertia. The rotation axis tracks the maximum principal inertia axis (PIA) of the non-hydrostatic inertia tensor as fast as adjustment of the hydrostatic bulge allows.

Paleomagnetism, Polar Wander, Fig. 1 Diagram illustrating polar wander on a quasi-rigid planet (After Goldreich and Toomre 1969). The beetles represent mass anomalies that change with time (drifting plates or mantle heterogeneities), inducing changes in the principal non-hydrostatic moments of inertia. The coordinate system attached to the (slowly deforming) solid planet moves with respect to the rotation (or spin) axis

Measure of True Polar Wander

The position of the rotation axis depends on the time scale. According to astronomers and geodesists, polar wandering is occurring at present. For instance, a determination by Gross and Vondrak (1999) uses the star catalog established from satellites during the past century. The result is a mean drift of the Earth's rotation pole over the period 1900–1992 of 107 mm/year along the direction of the 79°W meridian.

It has also been proposed that this long-term polar wander is largely due to post-glacial rebound, i.e., lithospheric and mantle response to melting of ice (e.g., Sabadini and Peltier 1981; Mitrovica and Milne 1998). The pole is moving towards Hudson Bay, where a large ice mass melted and the lithosphere is currently rising.

On time scales longer than 10^6 years, TPW most likely reflects convection of the whole mantle expressed at the surface by horizontal plate motions Steinberger and O'Connell (2002), and paleomagnetism has become the primary source of information. The apparent polar wander paths from all the major plates are being defined with increasing accuracy, and their differences reflect continental drift and plate tectonics. This demonstration of the reality of "apparent" polar wander seen from any plate has led some to propose that the concept of "true" polar wandering might be irrelevant or unnecessary. Are remaining fractions in polar wander, which would be a characteristic of "Earth as a whole," and which would not be accounted for by plate tectonics, actually resolvable? The concept is worthwhile if a reference frame external to the plates themselves can be defined, in which there was significant motion of the pole. Most studies performed in the last two decades followed an approach, based on the possibility, originally suggested by Morgan (1972, 1981), that hotspots could provide a valid reference frame for the mantle. Its meaning and existence has been the subject of continued debate, up to this day.

Hotspots are active volcanoes apparently unrelated to plate boundaries, which have been active for tens of millions of years. Hotspots are supposed to be the surface manifestation of plumes, which have left traces in the form of nearly linear chains of extinct volcanoes on the plate(s), which passed over them. Morgan (1972, 1981) proposed that these plumes have a "deep" mantle origin: these convective instabilities may be anchored at least down to the transition zone and possibly all the way down to the core-mantle boundary. As a plate moves over such a plume, the relative motion can be described by a rotation about a pole. If hotspots are indeed fixed with respect to each other and are fixed within the mantle, then hotspot apparent polar wander describes the wander of the Earth's rotation axis with respect to the mantle. It is this motion of the pole with respect to the hotspots, assumed to act as a reference frame for the mantle, which has been taken as an estimate of true polar wander. Determining TPW requires the best

possible knowledge of APWPs of all plates (i.e., the best possible data base of paleomagnetic poles to determine the paleolatitudes and orientations of plates with respect to the rotation axis), of their relative motions (determined by marine magnetic anomalies and azimuths of transform faults), and finally the positions and ages of individual volcanoes along hotspot tracks on plates. Paleolatitudes of these seamounts are used for comparison to test model predictions.

APWPs and kinematic models were developed from the 1960s to the 1980s under the key assumption that when averaged over a sufficient amount of time, in excess of a few thousand years, the Earth's magnetic field could be described accurately by a geocentric axial dipole (so-called GAD hypothesis). Besse and Courtillot (1991, 2002), among others, proposed to blend two data sets: the paleomagnetic poles used to derive the APWPs and the oceanic data used to derive plate kinematic models. They used then available paleomagnetic and kinematic models and produced a “synthetic” APWP, which was defined with respect to South Africa and then transferred to all other plates. Motion of hotspots with respect to the plates (Müller et al. 1993) was then integrated to derive an estimate of TPW (Fig. 2).

The resulting TPW curve is shown in Fig. 3 with a 20 Myr time resolution (each point corresponds to the successive positions with respect to time of a hotspot presently situated at the North geographic pole). Points are shown with their 95% confidence circles every 10 Myr and every other point is statistically independent (estimates at 5 Myr intervals are also

available in that study). The first points, corresponding to the period 8–59 Ma, are all in the same quadrant, between 3.3° and 5.9° away from the present rotation pole, with 95% uncertainties ranging from 2° to 3.8° . They are not statistically distinct from each other and therefore could correspond to a standstill. A mean position can be calculated from all data points in that time window: It is found to lie significantly displaced from the pole. The youngest mean pole at ~ 5 Ma is also significantly displaced from the pole but not statistically different from the 55 Ma overall mean. It seems that TPW may have been negligible for an extended period of about 50 Myr, but accelerated a few million years ago, with a velocity on the order of 100 km/Myr. Prior to that, the path displays a succession of a standstill at 160–130 Ma, a quasi-circular track from 130 to 70 Ma, then the standstill at 50–10 Ma and the faster motion up to the present. The true polar wander rate between 130 and 70 Ma averages 30 km/Myr. True polar wander appears episodic in nature, with periods of (quasi) standstill alternating with periods of faster TPW. The typical duration of these standstill periods is on the order of a few tens of millions of years (50 Myr). Because of all the uncertainties in models of hotspot kinematics prior to ~ 130 Ma, it is not safe to place too much weight on behavior prior to that time. The major event since then is therefore the end of the 130–60 Ma period of relatively fast polar wander, with a standstill (i.e., no or little TPW) from 50 Ma (actually because of larger 95% confidence circles, possibly 80 Ma) to 10 Ma.

Paleomagnetism, Polar Wander, Fig. 2 How mantle TPW is determined: At Time T0, a deep plume (located arbitrarily under the North Geographic Pole) produces a volcano V0 on an oceanic plate. In the hypothesis of a Geocentric Axial Dipole field, a magnetization of inclination $I_0 = 90^\circ$ is fossilized in the lavas (the inclination (I) depends on the colatitude (θ) such as $\text{TgITg}\theta = 2$). Time T1: the oceanic plate has moved southward and a hotspot trace is formed, but the Plume remains at the same position (i.e., no mantle TPW). A new volcano (V1) is fed and

records the same 90° inclination (I_1) as in the volcano V0. Time T2: an episode of TPW occurs: the plume is tilted southward (with the rest of the mantle). The third volcano V2 will fossilize a lower inclination than V0 and V1. Later on, a paleomagnetist will measure past inclinations in lavas: as lithosphere only moves on the mantle, volcanoes will record the same inclination; the plume remains stationary. In case of TPW, the difference of paleolatitudes deduced from measured inclination will indicate the amount of motion

Paleomagnetism, Polar Wander, Fig. 3 True polar wander paths deduced from the hotspot model of Müller et al. (1993) going from the Present back to 130 Ma, and that of Morgan (1981) going from 130 back to 200 Ma, with associated 95% confidence ellipses (shaded light gray); 20 Ma sliding window. Ages are in Ma and correspond to the actual mean age of the data in the corresponding window, which is why they are not regularly distributed when the original time windows were. Note that the external circle is at 50° latitude. (After Besse and Courtillot 2002)

However uncertain, evidence for the fact that Earth emerged from a long standstill to enter a new period of faster polar wander in a different direction 10 Ma ago (~5 Ma at the higher resolution) is particularly interesting. That period would then still be going on. The youngest pole at ~5 Ma, taken at face value, would imply a TPW rate of 130 km/Myr in the direction ~15°W (with a large azimuthal uncertainty from 10°E to 40°W, due to proximity of the 5 Ma pole to the present rotation axis). The reasonable agreement with recent astronomical determinations (107 km/Myr in the direction 79°W, with a possible range from 65°W to 85°W) has reinforced the idea that this might be a valid estimate and that TPW direction and rate might have been rather stable over the last five million years corresponding to significant, large-scale changes in ice cover. Ice is not considered to have played a significant role before. It was absent prior to ~30 Ma.

A legitimate concern regarding the above conclusions is due to the fact that the analysis is not truly global, in that it fails to encompass the Pacific plate. Petronotis and Gordon (1999) have compiled an APW path (nine poles from 125 to 26 Ma) for the Pacific plate, based on the analysis of skewness of ocean crust magnetic anomalies and on seamount magnetic anomaly modeling. Using the Pacific plate versus hotspot kinematic model of Engebretson et al. (1985), based on dating of volcanoes that are part of hotspot tracks such as Hawaii, Louisville, or MacDonald, Besse and Courtillot (2002) have

Paleomagnetism, Polar Wander, Fig. 4 Comparison between the “Indo-Atlantic” (open dots and dashed line) and “Pacific” (squares and solid line) TPW Paths. The arrow shows the mean pole motion between 1900 and 1990. (After Besse and Courtillot 2002)

determined a corresponding 125–26 Ma “Pacific hotspot only” TPW curve. The “Pacific” and “Indo-Atlantic” TPW curves are compared in Fig. 4. This comparison is interesting because the data sets they are based on are entirely different and independent.

Despite some significant differences, it is worth emphasizing that the two curves are altogether similar in shape (tracks, amplitudes, azimuths), particularly the 300° longitude trending track from 130 to 70 Ma, though the two are offset (in the same general direction) by about 7°. More precisely, the confidence intervals intersect (though means are not in the intersection) near 125, 90, 60, 40, and 30 Ma. The main differences occur between 80 and 70 Ma: the 82 and 65–72 Ma poles derived from Petronotis and Gordon (1999) and the 77 and 67 Ma poles derived by Besse and Courtillot (2002) are clearly distinct. Tarduno and Cottrell (1997) and Tarduno et al. (2003), however, expressed doubts on the reliability of APWPs for an oceanic plate, such as the Pacific, when they are based solely from inversions of magnetic surveys over seamounts and/or analysis of skewness of marine magnetic profiles. They have determined the paleolatitude (based on inclination-only data from cores) of the 81 Ma old Detroit Seamount, which is part of the Emperor chain, and noticed that the paleolatitude is distinct from that based on the 81 Ma pole of the Pacific APWP (Sager and Pringle 1988) based on seamount anomaly poles. Tarduno and Cottrell (1997) exclude the possibilities of inadequate

sampling of secular variation, bias due to unremoved overprints or off-vertical drilling. Di Venere and Kent (1999) and Cottrell and Tarduno (2000) argue that the reliability of the Pacific paleopoles based on either modeling of seamount magnetic anomalies or determination of skewness of marine magnetic anomalies should be considered suspect. Both are prone to numerous biases and could yield errors in excess of 10° in the position of the mean poles derived from them. This debate is not closed.

Is a Reference Frame Based on Hotspots Valid?

Another question discussed in the last decade is Pacific hotspot fixity with respect to one another and to the “Indo-Atlantic” hotspots. Norton (1995) has suggested that the famous 43 Ma Hawaiian bend in the Hawaiian–Emperor hotspot track was actually a “nonevent,” i.e., indicated a change in motion of the Hawaiian hotspot with respect to the mantle rather than a change in Pacific plate motion. Koppers et al. (2001) find that the 0–43 Ma Hawaiian and Foundation seamount trail pair is the only one compatible with the fixed hotspot hypothesis. The 43–80 Ma Emperor/Line pair shows particularly large discrepancies, requiring motions of at least 30 km/Myr. Koppers et al. (2004) studied $^{40}\text{Ar}/^{39}\text{Ar}$ age progressions of the Hawaiian and Louisville hotspot tracks. They showed that the progression is nonlinear and can be better fitted with a moving hotspot model rather than a fixed hotspot frame of reference. The primary Hawaiian and Louisville hotspots did not move in concert, showing significant inter-hotspot motion between 80 and 47 Ma. While the Hawaiian hotspot experienced a substantial 15° southward motion prior to 47 Ma (Tarduno et al. 2003), the Louisville hotspot is predicted to have experienced an eastward motion of 5° during the same geological period, followed by a minor 2° latitudinal shift over the last 30 Myr. Clouard and Bonneville (2001) showed that Pacific seamounts are actually created by different processes, many being short-lived. Only the Hawaii and Louisville chains qualify as long-lived hotspots that can robustly be tested for fixity. Their preferred explanation for this is southward drift of Atlantic hotspots prior to ~95 Ma. Courtillot et al. (2003) reanalyzed the characteristics of the world catalog of some 50 hotspots. They suggest that surface hotspots on Earth may have three distinct origins with only seven “primary” hotspots (Hawaii, Easter, Louisville, Iceland, Afar, Reunion, and Tristan da Cunha) originating from the deepest part of the lower mantle, possibly anchored on chemical heterogeneities deposited in the D'' layer. Courtillot et al. (2003) found no evidence for inter-hotspot motion significantly larger than 5 km/Myr either within the Pacific hemisphere or the Indo-Atlantic hemisphere hotspots. Such rms velocities of 5 km/Myr or less, i.e., an order of magnitude less than rms

plate velocities, are to first order “small.” So, some primary hotspots indeed seem to provide a quasifixed frame in each hemisphere over the past 80–100 Myr.

Was there then any motion between the two hotspot ensembles? This raises the well-known difficulty of establishing a reliable kinematic connection between the two hemispheres through Antarctica. This has been addressed by Raymond et al. (2000). Based on updated kinematics (assuming that there is no missing plate boundary or unaccounted for motion between East and West Antarctica), these authors predict the location of the Hawaiian hotspot back in time, under the hypothesis that Reunion and Hawaii have remained fixed with respect to each other; for this, they use the dated tracks left on the African and Indian plates by the Reunion hotspot since it started as the Deccan traps 65 Ma ago. The plot of misfit between the predicted and observed positions for Hawaii as a function of time indicates that the two hotspots have actually drifted slowly, at ~10 km/Myr, for the last 45 Myr, but at a much faster rate (~50 km/Myr) prior to that, vindicating conclusions of Pacific hotspot motion reached by Tarduno and Cottrell (1997) or Tarduno (2007). Courtillot et al. (2003) conclude that the primary hotspots may form two distinct subsets in each one of the two geodynamically distinct hemispheres. Each subset would deform an order of magnitude slower than typical plate velocities. The two subsets would have been in slow motion for the last 45 Myr, but in faster motion prior to that.

Using their paleomagnetic results from Marie Byrd Land in West Antarctica, Di Venere and Kent (1999) demonstrated that some motion must have taken place since 100 Ma between West (Marie Byrd Land) and East Antarctica; they concluded that this motion cannot account for more than 20%, and possibly as little as 4% of the 14.5° offset between the observed and predicted positions of the 65 Ma Suiko seamount on the Emperor continuation of the Hawaiian hotspot track. They also discussed the integrity of the Pacific plate and the role of missing plate boundaries and errors in kinematic plate circuits, and find that they play a small role. Di Venere and Kent (1999) concluded that most of the apparent motion between the two main groups of hotspots is real, with an average drift of about 25 km/Myr since 65 Ma. Steinberger et al. (2004) have combined hotspot motion in the large-scale flow field of the mantle and intraplate deformation to account for most of the post-65 Ma misfits between computed and observed hotspot tracks. Only a combination of the two effects (hotspot motion and intraplate deformation) successfully predicts the geometry of the four selected seamount chains in the Pacific and Indo-Atlantic hemispheres. If correct, this analysis at the same time invalidates the notion of a reference frame or of separate hemispheres and replaces it with limited, predictable, inter-hotspot motion. But TPW can still be calculated. The Hawaiian hotspot would have moved faster between 80 and 50 Ma, and at the same time TPW

would have been faster prior to 50 Ma. TPW alone would account for paleolatitudinal changes of the Reunion hotspot, whereas the two effects would be required for the Hawaiian hotspot.

The estimate of true polar wander (TPW) over the last 200 Myr is thus still a matter of strong debates, as recalled above, being based only on hotspots from the Indo-Atlantic hemisphere. The TPW curve estimated using Pacific-only data is similar to the Indo-Atlantic TPW, seemingly validating to first order the concept that TPW is a global phenomenon. On the other hand, Besse and Courtillot (2002) suggest that TPW pole positions for the two hemispheres are significantly displaced between ~50 and ~90 Ma. Hotspot tracks become fewer and more uncertain as one goes back in the past and pre-130 Ma TPW estimates should be regarded with caution. However, there are strong indications (Besse and Courtillot 2002) that the phase of true polar wander, which ended around 50 Ma, may have started ~130 Ma ago.

Modeling of True Polar Wander

In an early attempt, Ricard et al. (1993b) and Richards et al. (1997) derived a model of mantle density heterogeneities based on plate motions recorded by the ocean floor, including slabs crossing the upper/lower mantle transition zone slowing down by a factor between 2 and 5. Based on this, they computed a synthetic geoid, which agreed rather well with observations, provided viscosity increased by a factor 40 going from the upper to the lower mantle. Changes in the degree 2 geoid should reflect the history of the inertia tensor and therefore TPW as revealed by paleomagnetism. They predicted TPW velocities on the order of 300 km/Myr in the direction 130°W, much larger than observed rates. Their three-layer model could not account simultaneously for the present-day geoid and observed TPW.

In other studies, seismic tomography has been used to infer 3D maps of density heterogeneities that drive flow in the viscous mantle. Steinberger and O'Connell (1997, 2002) have developed an algorithm to calculate changes in the Earth's rotation axis for rather general viscoelastic Earth models. Their model combines hotspot motion, polar wander, and plate motions in a single dynamically consistent model, allowing all effects to be simultaneously determined and their relative effects sorted out. Changes in rotation are due to advection of "realistic" density anomaly distributions inferred from a number of seismic tomography models in a "realistic" flow field constrained by observed plate kinematics at the surface. Steinberger and O'Connell (2002) compare their model results for a number of tomographic models and discuss the effects of compressibility, deep mantle viscosity, thickness of a high viscosity layer in the deep mantle, and chemical boundaries on rates of TPW. Their TPW estimates

are in qualitative agreement with observations for the last 100 Ma. Steinberger and Torsvik (2010) modeled the present-day non-hydrostatic inertia tensor by combining contributions due to large low-shear velocity provinces in the lowermost mantle and due to subduction and found a spin axis at 67°N, 96°E (north Siberia). The distribution of recent subduction, with largest amounts in the northwest Pacific (beneath East Asia) and the southeast Pacific (beneath South America), adds a secondary contribution that moves the spin axis toward the observed poles.

Rouby et al. (2010) also investigated the effect of internal mass redistributions on the position of the Earth's rotational pole for the last 120 Myr. They also used a geodynamic model based on plate reconstructions and estimated the location and rate of subducted slabs under the assumption that they sink vertically into the mantle (Fig. 5). The new model takes into account the effect of large-scale mantle upwellings derived from tomography (one is situated under Africa, the other, nearly antipodal under the Pacific Ocean). The temporal variation of the mantle density heterogeneities was essentially found to reflect changes in subduction history. Because the tomographic images seem to show that subducted plates do not systematically reach the CMB, they investigated the influence of the depth down to which these plates retain significant density contrast with respect to the surrounding mantle on the present-day geoid and on the temporal evolution of the Earth's PIA (we recall the rotational axis is aligned to the maximum PIA). They proposed a model, which yields to a present-day geoid in good agreement with the observed one. The associated minimum principal inertia axis seems to be relatively stable since 120 Ma and close to Africa, within the upwelling (Fig. 6). Their model displays that some of the features of the computed TPW, which are directly linked to the temporal evolution of the subductions, are reminiscent of observed phases of slow and fast true polar wander, with similar peak velocities. Although their computed TPW is almost in the same meridian as the observed one, the poles are still drifting in the opposite direction, as was already the case for Ricard et al. (1997).

An Integrated Explanation for Polar Wander?

Let us now put this study in the broader context of the history of the Earth's rotation.

Paleomagnetic indications that would support rather fast true polar wander in pre-Mesozoic time have been put forward by Van der Voo (1994; with rates between 70 and 110 km/Myr) and for very fast true polar wander by Kirschvink et al. (1997; with rates in excess of 600 km/Myr in the early Cambrian). Recall that Steinberger and O'Connell's (2002) numerical models place an upper limit of about 100 km/Myr on TPW velocity. For pre-Jurassic time,

Paleomagnetism, Polar Wander, Fig. 5 Subduction zones at the Earth surface, every 40 Myr, since 200 Myr, superimposed to the present-day final computed geoid (degree 2–12). The *square* represents the mean center of small circles fitting the subductions zones. (After Rouby et al. 2010)

Paleomagnetism, Polar Wander, Fig. 6 Principal Inertia Axes since 120 Myr (dots every 10 Myr, stars denote present-day values) for our mantle density heterogeneities model. The corresponding present-day geoid (degree 2–12) is also shown. (After Rouby et al. 2010)

ocean floor has been destroyed (together with evidence of plate kinematics and most hotspot traces) and TPW cannot be estimated in the way indicated above. Evans (2003) proposes to obtain a crude estimate of TPW in the case when TPW velocity would have been much faster than between-plate

motions. Kirschvink et al. (1997) and Evans (2003) discussed the fact that the Earth may have in the past catastrophically exchanged two of its principle axes of inertia (inertial interchange true polar wander or IITPW), i.e., the whole lithosphere (and mantle) may have rotated by some 90° in only a

few million years, bringing for instance parts of the Earth that were close to the poles at the Equator. Evans (2003) interpreted the large rotations as TPW about a common, long-lived, minimum inertial axis ($I_{\min}$) near eastern Australia, which may also be regarded as the prolate axis of Earth's figure, inherited from Rodinia (Fig. 7).

Satolli et al. (2007) on the basis of a high definition magnetostratigraphy in the Apennines argued that a major trend of the “mean” plate motion since at least 200 Ma can be described as large successive clockwise or counter-clockwise rotations linked to TPW, and roughly centered on Africa, this last plate being a “central plate” from which most continents have diverged since the break-up of Pangea (Fig. 8). An animated sequence derived from Besse and Courtillot (1991) APWP displays visually those features available at <http://www.ipgp.fr/~besse/pw>. Steinberger and Torsvik (2008) have also found that the global axis of rotation for plates since 250 Ma also roughly centered in Africa, and argued that they may also correspond to maxima of the degree 2 non-hydrostatic geoid, corresponding to the mantle upwellings.

Le Pichon and Huchon (1984) already remarked that during Late Triassic about 200 Ma ago, the outlines of Pangea lay along a great circle passing through the paleopoles of rotation and also noticed that the present geoid also displays hemispheric symmetry with an axis located in the equatorial plane. The stability of subduction zones back to the middle of the Paleozoic in a nearly N-S plane was also recognized by Collins (2003). All these studies pointed out a strong link

between pole positions and the geometry of the convection: this coincidence might be explained by a deep-seated, quadrupolar convection as was first advocated by Busse (1983). Rouby et al. (2010) addressed this question by computing a present geoid day (degree 2–12) using the plate model described above (Figs. 5 and 6).

The persistent location of subductions in the western Tethyan and Pacific regions for at least 250 Ma (and possibly earlier according to Collins) have generated a ring of downwelling material inducing hot return flows (the upwellings mentioned above) confined to two main regions (presently Indo-Atlantic and Pacific). This geometry defines the location of PIAs and pins the minimum PIA in the region of upwelling. This large zone is roughly centered on the equator also close to the maxima of the degree 2 non-hydrostatic geoid. The minimum PIA has been relatively stable since 120 Ma and close to Africa. On the contrary, both the maximum and intermediate PIAs have moved in a plane perpendicular to Africa along a meridian corresponding to the large-scale pattern low of the geoid. This meridian seems to be stable with time, similar to the large-scale pattern of subduction around the Pacific and western Tethyan zone of subductions.

The temporal evolution of the rotation axis is that of the maximum PIA. Oscillatory polar wander is attributed to TPW about a common, long-lived minimum inertial axis, which would be the prolate axis of Earth figure, inherited from the past plates/continent configurations and following the quadrupolar convection model of Busse (1983).

This peculiar pattern may constitute a long-lived feature of our planet, at least since 200–250 Ma, which forces continents to be roughly in an EW position, on a single hemisphere bounded by a plane containing the rotation axis, with the Earth's rotational pole not far from the main ring of subduction zones. TPW (and possibly APW) may occur around a nearly equatorial euler pole (axis) of rotation, driven by slight changes of magnitude between the maximum and intermediate PIAs, principally caused by subduction locations and rate changes with time. This view is coherent with the successive CW and CCW rotations of all continents (including the Pacific Ocean) observed by Evans (2003), Satolli et al. (2007), and Steinberger and Torsvik (2008) around a point located somewhere in Africa and close to the equator for these last two authors.

Paleomagnetism, Polar Wander, Fig. 7 Terminal Proterozoic to late Paleozoic apparent polar wander path for Gondwanaland. Oscillatory APW rotations are interpreted as TPW about a common, long-lived, minimum inertial axis (near eastern Australia). (After Evans 2003)

Conclusions

For the time being, the hypothesis that TPW is a go-stop-go phenomenon, with long standstills in the tens of millions of years, and periods of faster, rather uniform polar wander at

Paleomagnetism, Polar Wander, Fig. 8 Global continent and ocean reconstructions, from 180 Myr to present-day, based on techniques and APWPs described in Besse and Courtillot (2002). Magnetic anomalies are from Royer et al. (1992), the 150 and 130 Myr frames from Satolli et al. (2007). A major trend of the “mean” plate motion since at least

200 Myr can be described as successive clockwise or counter-clockwise rotations (linked to TPW), and roughly centered in Africa (close to the minimum PIA, see Fig. 8). The blue arrow indicates the direction of rotation until the next reconstruction. (After Rouby et al. 2010)

velocities often not exceeding 30 km/Myr, cannot be discounted. Evidences for superfast events at any time in the past remain to be demonstrated.

The similarity between TPW estimates for the Pacific plate and the rest of the world, which are based on completely different and independent data sets, may be taken as support to the idea that small yet significant TPW, on the order of 10° , occurred since the Cretaceous, though it still requires careful verification.

Most current modeling still fails to some extent to account for the slow values of typical TPW velocity (0–30, and rarely up to 100 km/Myr), and even more so to account for the prolonged (~50 Myr) periods with almost no TPW (standstills). Steinberger and O’Connell (2002) give reasonable velocities but predict smooth evolutions, rather than the

alternating episodes, revealed by paleomagnetic data. Rouby et al.’s (2010) model restores the present geoid, displays some of the features of computed TPW that are directly linked to the temporal evolution of subductions, reminiscent of observed phases of slow and fast true polar wander, with similar peak velocities, but the poles are still drifting in the wrong direction, as was also the case for Ricard et al. (1997).

TPW seems to be linked to a pattern of quadrupolar convection permanent (at least on periods of time in excess of 200 Ma). If the two upwellings remain more or less in the same locations, the pole may move on the great circle perpendicular to the axis they form, the system being stabilized by subductions not far from the pole. These concepts remain to be tested for earlier periods of time.

The importance of the Pacific plate and severe limitations on presently available data from that plate, the fact that the global paleomagnetic database still is quite scant for certain continents and time windows, the fact that many hotspot traces are not yet sufficiently constrained in terms of age and paleolatitude, all point to the need for many more direct (paleomagnetic) measurements as opposed to indirect/remote sensing determinations of magnetization direction (i.e., “skewness” or “seamount” data).

The reason for the discrepancies between models and data could be due to the quality of reconstruction of the Pacific Ocean (specially before 130 Ma) and its relationship with bordering continents, and hence, the poor knowledge of the exact amount of subduction at a given time (to which these kind models are so sensitive). Some of this information is unfortunately lost forever, since large parts of the Pacific Ocean have been subducted.

Future research should aim to understand the discrepancies between observation and computations in order to estimate possible uncertainties on the associated mantle mass anomalies by testing other reconstructions. It will be particularly useful to build a single reference frame for both Indo-Atlantic and Pacific hemispheres: this implies that one must be able to use Antarctica to link the two hemispheres. This will not be easy, given the poor knowledge of deformations suffered by the continent and the possibility of existence of active margins on its Pacific border.

Paleomagnetism, Principles

William Lowrie

Institute of Geophysics, Swiss Federal Institute of Technology, Zürich, Switzerland

Definition

Paleomagnetism is the study of the Earth's ancient magnetic field, based on the measurement and analysis of the *remanent* (i.e., permanent) magnetization acquired by rocks during their formation.

Introduction

Paleomagnetism provides data that are important in the interpretation of geological processes. For paleomagnetic results to be reliable for this purpose, several stringent conditions must be fulfilled. First, a rock under investigation must be able to record accurately the direction and intensity of the weak geomagnetic field during its formation or later alteration. This requires an understanding of the magnetic properties of rocks and minerals. Second, the age of acquisition of the rock's magnetization, or its subsequent alteration, must be well known. Field tests based on the local and regional geology of a sampling site are valuable in this respect. Third, the remanent magnetization of the rock must possess outstanding stability in order to be able to persist unchanged for geological eons.

The Geocentric Axial Dipole

The Earth's magnetic field has been measured and analyzed systematically since Carl Friedrich Gauss and Wilhelm Weber established a global network of geomagnetic observatories in the late 1830s. In the past 40 years, Earth-orbiting satellites carrying magnetometers have greatly increased the amount of high-quality magnetic data and also improved the global coverage. The measurements are analyzed using spherical harmonic analysis to define the potential W_i of the field of internal origin by the series

$$W_i = R \sum_{n=1}^N \sum_{m=0}^n \left(\frac{R}{r}\right)^{n+1} (g_n^m \cos m\phi + h_n^m \sin m\phi) P_n^m(\cos \theta)$$

The Gauss coefficients g_n^m and h_n^m in this series can be computed accurately to a very high degree n . For example, a

combination of satellite data with marine magnetic and aeromagnetic data produced a high-resolution model of the field (NGDC-720) with Gauss coefficients g_n^m and h_n^m up to degree $n = 720$. The high-degree terms with $n \geq 15$ are attributed to magnetic sources in the lithosphere. The Gauss coefficients with $n \leq 14$ define the International Geomagnetic Reference Field (see ► “Geomagnetic Field, IGRF”), which is the global magnetic field that originates in the Earth’s core.

The most important part of the magnetic field is the dipole component, which corresponds to the terms with $n = 1$. All terms with $n \geq 2$ in the spherical harmonic analysis are referred to collectively as the *non-dipole field*. The term g_1^0 is the strongest component of the field; it represents a magnetic dipole located at the center of the Earth and aligned with the rotation axis. The coefficients g_1^1 and h_1^1 correspond to orthogonal equatorial dipole components. Together, the three terms with $n = 1$ describe a geocentric dipole whose axis is inclined to the rotation axis. At present the axial tilt is about 9° , and the geomagnetic pole does not coincide with the geographic pole. A compass needle aligns with the horizontal component of the magnetic field – the magnetic meridian – and not with the geographic meridian; the angular deviation is the *declination* (D), which varies from place to place on the Earth’s surface.

The *inclination* (I) of the magnetic field is the angle that a magnetic field line makes with the horizontal at the Earth’s surface. For a dipole field the inclination is related to the latitude λ of the observation site by the equation

$$\tan I = 2 \tan \lambda = 2 \cot p \quad (1)$$

In this equation $p = (90^\circ - \lambda)$ is the co-latitude of the observation site, i.e. the angular distance of the magnetic pole from the site.

The basic premise of paleomagnetism is the *geocentric axial dipole* (GAD) hypothesis. This postulates that the equatorial dipole components, together with the non-dipole field, average to zero when averaged over sufficiently long intervals of time, leaving only the GAD component as the geologically important record of the ancient field. Consequently, the magnetic pole position calculated in a paleomagnetic investigation defines the location of the paleogeographic axis. Discrepancies from the present axis are interpreted in terms of geological processes.

The dipole and non-dipole fields change slowly with time, a characteristic known as *secular variation*. Time-dependent changes of the Gauss coefficients are observed in repeated analyses of the recent field. Secular variations affect both the direction and the intensity of the field. It has been possible to reconstruct geomagnetic secular variation since the late sixteenth century by using the magnetic observations of mariners (Jackson et al. 2000). Moreover, the intensity of the geomagnetic field has decayed by about 5% per century since direct

measurements began about 180 years ago. The rate of decrease prior to 1840 may have been slower (Gubbins et al. 2006).

On a longer time-scale, fluctuations in magnetization direction and intensity that are not due to mineralogical variations have been documented in paleomagnetic analyses of sedimentary records. The changes take place over centuries and millennia and are called *paleosecular variations* to distinguish them from changes in the present and historic field. Figure 1 shows oscillations in both inclination and declination, compiled by averaging the magnetization directions measured in cores of sediments from British lakes. The sediments were dated using radiocarbon and palynological age determinations, which enabled correlation of their records from lake to lake and subsequent stacking. The figure represents paleosecular variation in direction of the geomagnetic field in Britain during the past 10,000 years.

For the GAD hypothesis to be valid, the paleosecular variations must average to zero over a few thousands of years, so that the inclination and declination of the magnetization recorded in a rock or sediment represent the GAD field at the time of their formation. A test of the hypothesis, carried out in cores of marine sediments deposited in the last 2.5 Million years, is illustrated in Fig. 2. The mean inclinations

Paleomagnetism, Principles, Fig. 1 Master curves of paleosecular variation of inclination and declination for the past 10,000 years, compiled from British lake sediments. (After Fig. 5 in Turner and Thompson 1981. Redrawn by permission of Oxford University Press)

Paleomagnetism, Principles, Fig. 2 The mean inclinations of magnetization in marine sediment cores are plotted against the latitude of each sampling site. (After Fig. 3 in Schneider and Kent 1990. Redrawn by permission of John Wiley and Sons. Copyright 1990 by the American Geophysical Union). The continuous curve is the theoretical relationship given by Eq. (1) for a GAD field. The small deviations are partly due to paleosecular variation that has not been averaged out, but systematic bias indicates persistent long-term quadrupole and octupole components

of magnetization measured in the sediments agree well with the values expected for a GAD field predicted by Eq. (1). However, the agreement is not perfect, and the optimum fit of a theoretical curve to the data is obtained when small geocentric axial quadrupole (g_2^0) and octupole (g_3^0) components are included, each equivalent to a few percent of the dipole. The magnetohydrodynamic theory of the origin of the geomagnetic field gives no rigorous theoretical justification for the GAD hypothesis or explanation of possible persistent zonal quadrupole and octupole components. However, experimental tests of the hypothesis indicate that it is a good first-order model of the time-averaged geomagnetic field. The discrepancies may be due to a geological factor, such as sedimentary inclination flattening (Tauxe 2005).

Rock Magnetism

The ability of rocks and sediments to acquire a stable magnetization that preserves the direction of the GAD is due to the presence of specific magnetic minerals that behave in a similar way to ferromagnetic metals. Ferromagnetism is the type of magnetic behavior found in iron and similar metals. It is characterized by a Curie temperature, above which the ferromagnetism disappears. Ferromagnetic metals are strongly

magnetic. They have properties such as magnetic hysteresis, saturation magnetization, and remanent magnetization. The important rock-forming minerals exhibit *diamagnetism* or *paramagnetism*, which are very weak forms of magnetism that do not show magnetic hysteresis. Because they cannot acquire a remanent magnetization, they play no part in paleomagnetism. A few minerals – iron oxides and sulfides – exhibit *ferrimagnetism*, which is a form of ferromagnetic behavior associated with the mineral's crystal structure. Ferrimagnetic minerals are able to acquire a *remanent magnetization*. This means that when the magnetic field changes or is removed, they retain a magnetization imparted by it. Although they occur in tiny concentrations in rocks, the paleomagnetic properties of a rock or sediment are due to their presence.

The most common ferrimagnetic minerals are members of the titanomagnetite and titanohematite solid solution series, whose end-members are magnetite and hematite, respectively. Magnetite is usually a primary magnetic mineral coeval with the origin of igneous rocks or pre-dating the deposition of sediments. Hematite, pyrrhotite, and greigite are other important magnetic minerals, but they often originate in the rock after its formation, so the age of their magnetization can be dubious.

The magnetization of a rock is due to the partial alignment of the magnetic moments of its constituent grains. Within any particular grain, the magnetic moment has a direction, conventionally called the “easy” direction of magnetization, which is determined by the magnetic anisotropy of the grain. This, in turn, depends on the intrinsic magnetic properties of the magnetic mineral. For example, magnetite has a cubic structure and a comparatively strong spontaneous magnetization ($M_s = 4.8 \times 10^5 \text{ A m}^{-1}$). The shape of a non-spherical magnetite grain dominates its anisotropy so that the magnetic moment favors the direction of the longest axis of the grain. In contrast, hematite has a rhombohedral structure and a weak spontaneous magnetization ($M_s \sim 2.5 \times 10^3 \text{ A m}^{-1}$). It has a strong magnetocrystalline anisotropy related to the crystal structure that causes the magnetic moment to lie in the basal plane of the crystal at room temperature.

In very fine grains of ferrimagnetic minerals, the anisotropic magnetic energy of the grain constrains the spontaneous magnetization direction to lie along an easy direction, and the entire grain is uniformly magnetized as a *single domain*. The high spontaneous magnetization of magnetite creates anisotropic magnetostatic energy related to the particle shape. The theoretical range of single domain sizes in magnetite is narrow, from about 0.03 to 0.1 μm in equant grains and up to about 1 μm in elongate grains. In contrast, hematite has a large magnetocrystalline anisotropy energy, and single domain grain sizes may extend up to 15 μm . The magnetization of a single domain particle is very stable, because to change it requires rotating the entire uniform

magnetization of the grain against the grain anisotropy. The magnetic field required to reverse the direction of magnetization of a single domain grain is its *coercivity* B_c . In magnetite, this field is commonly in the range 10–100 mT, but may be up to 0.3 T in acicular grains. The magnetic properties of hematite are variable and its maximum coercivity can exceed 2 T. Because of their stable remanent magnetizations, single domain particles play a very important role in paleomagnetism.

When the grain size of a magnetic mineral exceeds a critical value, the magnetostatic energy of the grain becomes too large for the grain to exist as a single domain and the magnetization subdivides into oppositely directed domains. *Multidomain* magnetizations can be changed by merely moving the wall between adjacent domains, so are less stable against change than single domains. As a result, coarse-grained rocks are often unsuitable for paleomagnetism. Laboratory methods have been developed to identify the magnetic minerals in a rock, and to evaluate whether the grain size is single domain, multidomain, or intermediate (the latter category being termed pseudo-single domain).

The magnetic moment of each grain in a rock aligns with a magnetizing field as closely as permitted by the magnetic anisotropy of the grain. Thermal energy acts to destroy the partial alignment of magnetic moments. As a result, a magnetization that originally has the value M_0 decays exponentially with time, so that after time t the remaining magnetization M_r is given by

$$M_r = M_0 \exp(-t/\tau)$$

The rate of decay is governed by the *relaxation time* τ , which is a function of the magnetic properties of the grain and the temperature T . For single domain grains of magnetite

$$\tau = \frac{1}{f} \exp\left(\frac{VB_c M_s}{2kT}\right) \quad (2)$$

Here f is a frequency factor ($\sim 10^9 \text{ s}^{-1}$) related to the vibrational frequency of the crystal lattice; V is the volume of the grain, B_c its microscopic coercivity, and M_s its spontaneous magnetization; k is Boltzmann's constant. A single domain grain of magnetite, 30 nm in diameter, has a relaxation time of about 10^9 years at 20 °C. Other ferrimagnetic minerals can also carry magnetizations that are very stable against thermal decay. The high stability enables a rock to retain the remanent magnetization it acquired during rock formation for very long intervals of geological time. The relaxation time of the magnetization decreases with increasing temperature and with decreasing grain size. Thus, heating during tectonic deformation, or a change of grain size or mineral chemistry as a result of weathering, can modify or destroy a primary remanent magnetization.

Remanent Magnetizations

The development of paleomagnetism as a scientific discipline was made possible by the invention in the early 1950s of the astatic magnetometer, a device that was able to measure accurately the weak magnetizations of rocks. The instruments commonly used in modern paleomagnetic laboratories are spinner magnetometers and cryogenic magnetometers, which are very sensitive and can measure the weak magnetization of a rock very quickly. The concentrations of ferrimagnetic minerals are low, so rocks have very weak remanent magnetizations, measuring typically $\sim 10^{-1} \text{ A m}^{-1}$ for a basaltic lava and $\sim 10^{-3} \text{ A m}^{-1}$ for a pelagic limestone. The mechanism by which a rock becomes magnetized in the Earth's magnetic field has a strong effect on the intensity of the remanent magnetization it acquires.

When an igneous rock forms, its temperature is initially well above the Curie temperature of ferrimagnetic minerals (e.g., 580 °C in magnetite, 675 °C in hematite). The magnetic behavior is paramagnetic, incapable of retaining a magnetization. As it cools below the Curie point, the magnetite or hematite becomes ferrimagnetic. At high temperature, the relaxation time is short and the magnetic behavior is classified as *superparamagnetic*. With further cooling the relaxation time increases rapidly. A few tens of degrees below the Curie point a *blocking temperature* is reached, at which the relaxation time is so large that the magnetization becomes blocked by the anisotropy of the grain. If this occurs in a magnetic field, the ferrimagnetic grains acquire a *thermoremanent magnetization* (TRM) in the direction of the field. Equation (2) controls this process and ensures that the TRM has a high stability. On the other hand, if subsequent chemical alteration of the grain occurs, the grain volume V or spontaneous magnetization M_s may alter, which – again according to Eq. (2) – can give rise to a new *chemical remanent magnetization* (CRM). This can be an undesirable stable secondary component.

Sedimentary rocks that form from slowly deposited sediments can often be excellent archives of the ancient magnetic field. Magnetite grains form a tiny fraction of a sediment (e.g., less than 0.01% of a limestone). They acquire a partial alignment with the magnetic field in which they settle, forming a *depositional remanent magnetization* (DRM). In some very fine-grained sediments, further magnetite alignment takes place in the water-logged pore spaces between the non-magnetic matrix minerals. The sedimentation rates of pelagic marine sediments are very low and paleosecular variations are in principle averaged out within the size of a standard 1-in paleomagnetic sample. However, in lake sediments, the sedimentation rate is much higher and it is possible to study both the paleosecular variation (Fig. 1) and paleoclimatic effects in these sediments. Shallow-water marine limestones also have a relatively high deposition rate, but the detrital and biogenic

fractions that supply the magnetite are diluted in these limestones and they tend to have weak or unstable remanent magnetizations. However, deep-water marine sediments with high sedimentation rates from the north Atlantic have been used to simultaneously match relative paleointensity variations and oxygen isotope records that reflect paleoclimate (Channell et al. 2009).

In a paleomagnetic study, special laboratory techniques are used to isolate the components of magnetization present in the rock and to identify the primary component (see ► “Paleomagnetism, Measurement Techniques and Instrumentation”). This is the remanent magnetization acquired during formation of the rock. The remanent magnetization of a rock in situ is called its *natural remanent magnetization* (NRM). It may contain a primary component of geological significance, but this can be accompanied by secondary components of later origin. These can arise from geological processes, but some may also be induced during sampling. The secondary components can partially – in extreme cases, completely – overprint the primary component. The components of a rock magnetization must be understood for a paleomagnetic analysis to have geological significance.

By progressively demagnetizing the samples, the structure of the NRM can be analyzed and stable components isolated. There are two main methods of achieving this. When a rock sample is placed in an alternating field (AF), the magnetizations of all domains with coercivity less than the peak field are randomized. If the peak field is slowly reduced to zero and the equipment is shielded from the Earth’s field, this part of the rock magnetization is demagnetized. The part that remains has been “magnetically cleaned.” If the procedure is carried out in progressively increasing peak fields, the NRM decay shows the components present. Similarly, when a rock sample is heated to a given temperature T , components that have lower blocking temperatures than T are thermally randomized. If the sample is then cooled in field-free space, this part of the NRM remains demagnetized. The progressive destruction of the NRM by AF or thermal demagnetization reveals the components present in the NRM. The stable primary component (also called the *characteristic magnetization*) is identified computationally by principal component analysis of the directions during magnetic cleaning (Kirschvink 1980) and graphically using vector diagrams (Zijderveld 1967).

In addition to the remanent magnetizations acquired in a geological process, synthetic remanent magnetizations may be imparted to rock samples in the laboratory for the purpose of identifying and describing the carrier of a paleomagnetic signal. If a sample is placed in a magnetic field, the magnetic grains with coercivity less than the field are realigned; when the field is removed, an *isothermal remanent magnetization* (IRM) is left in the sample. If the field is strong enough to magnetically saturate the sample, a *saturation IRM* ensues.

Another important laboratory magnetization is produced by placing a sample in an alternating magnetic field in the presence of a constant bias field. When the alternating field is reduced to zero, an *anhysteretic remanent magnetization* (ARM) is produced in the sample. Both IRM and ARM can be used in various ways to gain information about the magnetic mineral and its grain size.

For paleomagnetic results to be a valid record of the ancient magnetic field, it is important to know that the remanent magnetization has the same age as the rock. Identification of the magnetic mineral is important, but this is not a sufficient criterion to establish that the magnetization is likely to be unaltered. Field tests play a decisive role in establishing whether a magnetization component is primary or secondary. The most important are the structural fold test and the magnetic reversals test; less common, but also useful, are the conglomerate test and baked contact test.

The principles underlying the fold and conglomerate tests are illustrated in Fig. 3. Layers A and B are folded rocks, and layer C is a conglomerate layer of large cobbles. The *fold test* examines the directions of magnetization around a fold. If the magnetization of a formation is stable, as in layer A, its direction will change from site to site around the fold; if it is unstable, as in layer B, all sites in the layer will have a common magnetization direction.

If a sedimentary formation is deposited over a long time interval, or if a collection of similarly aged igneous rocks covers enough time so that both normal and reversed intervals of geomagnetic polarity are represented, the *reversals test* may be applied. If paleosecular variation is adequately averaged out, the reversed directions should be antipodal to the normal directions, as in Fig. 4.

Less commonly used are the conglomerate and baked contact tests. The *conglomerate test* examines whether the cobble magnetizations have random directions (Fig. 3), which would indicate that the magnetization of the parent formation

Paleomagnetism, Principles, Fig. 3 The fold and conglomerate tests of the paleomagnetic stability of magnetization directions. The cobbles in the conglomerate (layer C) have random directions of magnetization, which indicates these are stable. The directions are also stable in layer A, changing around the fold, but in layer B their uniformity indicates they have been remagnetized after folding

Paleomagnetism, Principles, Fig. 4 Positive reversals test in a section of the *Scaglia cinerea* formation in Umbria, Italy. The mean of 52 normal directions (solid points) has declination 340° , inclination 44° ($\alpha_{95} = 3.0^\circ$) and differs by less than 1° from the antipode of the mean of 64 reversed directions (open points), which has declination 159° , inclination -44° ($\alpha_{95} = 2.7^\circ$)

from which the cobbles derive is stable. The *baked contact test* is applied to igneous flows and intrusions. The heat of a lava dike can remagnetize the contact zone of a rock it intrudes, or on which it flows. If the paleomagnetic directions in the baked contact zone agree with those of the lava and differ from the rest of the host rock, the lava has a primary magnetic direction.

In each of these field tests, rigorous statistical methods are used to decide the significance of the magnetization directions.

Statistical Testing of Paleomagnetic Data

Paleomagnetic studies are based on a hierarchical sampling system. A comparatively small number of samples, n , is taken at each of N sampling sites in a geological formation of interest; N and n are each commonly around 10–20. Statistical tests are carried out on the measured data at each hierarchical level. Testing the significance of the results is based on a method developed by Fisher (1953) that represents the paleomagnetic directions as unit vectors. These can be visualized as a distribution of points on a sphere, represented by a stereographic plot. The vector mean of the unit vectors is the best estimate of the population mean direction. Fisher suggested that the probability density function P of the distribution of

deviations between individual sample directions and their mean direction is given by

$$P(\theta, \kappa) = \frac{\kappa}{4\pi \sinh \kappa} \exp(\kappa \cos \theta)$$

The “precision parameter” κ describes the dispersion of the points. If $\kappa = 0$, the directions are uniformly or randomly distributed; if κ is large, the points cluster tightly about their mean direction. The best estimate of κ is k , defined as

$$k = \frac{N - 1}{N - R}$$

in which R is the vector sum of the N unit vectors. In paleomagnetism, the level of 95% confidence is used to define a circle with radius α_{95} around the estimated mean direction. This means that there is a 95% probability that the true mean of the distribution lies within this circle. An approximate formula (McElhinny and McFadden 2000) for the radius of the circle of confidence, especially appropriate for the small numbers of samples or sites in a paleomagnetic study, is

$$\alpha_{95} = \frac{140}{\sqrt{kR}}$$

The statistical definition of a confidence circle around the mean direction allows comparison of a paleomagnetic result with other data of the same age and from the same region. It allows critical evaluation of the directions before and after tectonic corrections (the fold test), as well as the equivalence of antipodal directions in a reversals test. Statistical analysis lends authority to the results and is an important aspect of all paleomagnetic investigations. The statistical methods can be applied to paleomagnetic directions and also to distributions of paleomagnetic pole positions.

Virtual Geomagnetic Poles and Apparent Polar Wander Paths

Assuming the GAD hypothesis, the location of the magnetic pole at the time of formation of a given rock formation is coincident with the geographic pole. As a result of subsequent plate tectonic motions, the location of the paleomagnetic pole becomes displaced. When the magnetizations of the rocks are measured, they appear to have been magnetized by a pole at the displaced location, which is accordingly designated the *virtual geomagnetic pole* (VGP). The principle of locating a VGP from the measured declination and inclination of the stable component of remanent magnetization in a rock is illustrated in Fig. 5. First, the inclination is used to calculate the angular distance p to the magnetic pole, employing Eq. (1). This defines a circle with radius p centered on the sampling site; it is the locus of possible pole locations. The

Paleomagnetism, Principles, Fig. 5 Method for locating the virtual geomagnetic pole in a paleomagnetic study. The distance p to the pole is computed from the paleomagnetic inclination I ; the VGP is located at the intersection of the circle with radius p and the meridian with declination D

VGP is located at the intersection of this circle with the meridian defined by the declination; a magnetic pole at this location gives the measured inclination and declination at the sampling site.

The VGP positions of samples from geologically young rocks cluster near to the geographic pole, corresponding to the GAD hypothesis. Older rocks from the same continent give VGP positions that group well away from the present rotation axis. They plot systematically along a curved path, called an apparent polar wander (APW) path, which appears to trace the motion of the paleomagnetic pole relative to that continent. However, paleomagnetic data define different APW paths for each continent. Assuming the validity of the GAD hypothesis, the mean paleomagnetic pole at any time must lie on the rotation axis. The Earth has only a single rotation axis, so it follows that each APW path is a record of the motion of its continent relative to the rotation axis. The APW paths for different continents diverge because the continents have been displaced relative to each other. This motion of the continents was originally called “continental drift” and is the result of plate tectonics (see ► [“Plates and Paleoreconstructions”](#)).

The use of paleomagnetic data to trace continental movements is illustrated by comparing the APW paths for Europe and North America prior to the Jurassic. They have similar

shapes (Fig. 6a), particularly for the Upper Carboniferous (Cu) to the Upper Triassic (Tru). The relative motions of tectonic plates on the surface of the spherical Earth are described by rotating pairs of plates about a common pole, known as the *Euler pole* of rotation. For example, the Euler pole of the European and North American plates in Fig. 6a is close to the present-day geographical pole. The APW path of a continent is constrained to move with the continent. Thus, the Cu-Tru segments of the two APW paths can be made to overlap by a clockwise rotation of Europe through 38° about this Euler pole (Fig. 6b). This indicates that from the Upper Carboniferous to the Upper Triassic Europe and North America belonged to the same supercontinent, *Laurasia*, itself the northern part of *Pangea* (see ► “[Plates and Paleoreconstructions](#)”). Later segments of the APW paths diverge as a result of the relative motion between Europe and North America since the Early Jurassic.

Continental reconstruction based on paleomagnetic data requires that the APW paths are securely defined. In order to ensure this, stringent selection criteria have been developed to ensure that the paleomagnetic data accepted for incorporation into the reference database are of satisfactory quality (Table 1).

Magnetic Polarity Reversals

The geomagnetic field has reversed polarity numerous times, apparently spontaneously and randomly. The record of polarity reversals has been studied in detail in igneous and sedimentary rocks and in unconsolidated sediments. Beginning in the 1950s, systematic studies of paleomagnetic polarity were made in radiometrically dated lavas for the most recent 5 Million years of Earth history. The history of magnetic reversals was confirmed by investigations in slowly deposited marine sediments covering the same time interval. The agreement between the igneous and sedimentary polarity sequences established that the reversals are a geomagnetic phenomenon and not merely a rock magnetic artifact.

Intervals of constant normal or reverse polarity are called polarity *chrons*; they last typically for 5×10^4 years to 5×10^6 years. The chrons may be interrupted at irregular intervals by shorter polarity *subchrons* that last on the order of 10^4 years. The *transition* from one polarity to the opposite one is estimated to take about 3–7 thousand years, which is much shorter than a polarity chron or subchron. The polarity transition is accompanied by a decrease in intensity of the paleofield, which may last up to twice as long as the directional change. The polarity record also shows occasional large *excursions*, in which the magnetic pole appears to spend $\sim 10^3$ years in equatorial latitudes, but instead of completing a reversal it returns to its initial location on the rotation axis.

Paleomagnetism, Principles, Fig. 6 Reconstruction of earlier positions of Europe and North America based on APW paths. (After Fig. 5 in Van der Voo 1990a. Redrawn by permission of John Wiley and Sons. Copyright 1990 by the American Geophysical Union). In (a) the APW

paths are shown in present coordinates; in (b) the European continent has been rotated by 38° clockwise about the Euler pole shown in (a) to bring the Cu-Tru segments of the APW paths into coincidence

Paleomagnetism, Principles, Table 1 Reliability criteria for paleomagnetic data. Van der Voo (1990b) suggested that acceptable paleomagnetic data should meet at least 3 of the following criteria

No.	Brief description of reliability criterion
1	Well-determined rock age and a presumption that the magnetization has the same age
2	Sufficient number of samples ($N \geq 24$), adequate precision of directional grouping ($k \geq 10$), and confidence angle $\alpha_{95} \leq 16^\circ$
3	Progressive demagnetization that demonstrably includes vector subtraction information
4	Field tests that constrain the age of magnetization
5	Structural control and tectonic coherence with the craton or block involved
6	The presence of reversals
7	No resemblance to paleomagnetic poles of younger age (by more than a period)

The irregular pattern of polarity intervals forms a geological “fingerprint,” which can be used to date and correlate other magnetic polarity sequences in both igneous and sedimentary rocks, and in sediments. The most important application has been the interpretation and dating of marine magnetic anomalies. New oceanic lithosphere forms at oceanic ridge systems and is then transported away from the ridges by the sea-floor spreading process (see ► “Sea-floor Spreading”). As the basaltic lava of the ocean crust cools, it acquires a TRM parallel to the Earth’s magnetic field. Sea-floor spreading persists for millions of years at a ridge, during which the magnetic

field changes polarity many times. This leaves some blocks of oceanic crust normally magnetized parallel to the field while their neighbors are reversely magnetized. A sequence of positive and negative magnetic anomalies, corresponding to normal and reverse polarities of the oceanic crust, is observed over the ridges; from this pattern, the sequence of polarity of the Earth’s magnetic field is obtained. The oceanic polarity pattern correlates with the polarity sequence in lavas that have been dated radiometrically, thus the ages of magnetized blocks of the ocean floor can be determined. Knowing the distances of the polarity changes from the oceanic ridge, the rate of sea-floor spreading can be calculated.

Older reversal patterns have been dated by magnetostratigraphy. This entails stratigraphic sampling of a sedimentary section that has a uniform lithology and was deposited at a uniform rate. Standard paleomagnetic techniques are used to evaluate the characteristic direction of each sample and establish the existence of *magnetozones* of constant polarity. As is the case with paleomagnetic data, strict reliability criteria regulate the acceptance of a magnetic stratigraphy into a global database (Table 2).

An example of coordinated magnetostratigraphy and biostratigraphy that correlates well with marine magnetic reversal history is shown in Fig. 7. The *Scaglia cinerea*, a marly limestone in Umbria, Italy, was deposited in the Late Paleogene and acquired a DRM that preserves the direction and polarity reversals of the geomagnetic field during deposition.

Paleomagnetism, Principles, Table 2 Reliability criteria for magnetostratigraphy. Opdyke and Channell (1996) proposed that an acceptable magnetostratigraphic section should pass at least 5 of the following 10 tests

No.	Brief description of reliability criterion
1	Stratigraphic age known to the level of the stage, and associated paleontology presented adequately
2	Sampling localities placed in a measured stratigraphic section
3	Complete thermal or alternating field demagnetization performed, and analysis of magnetization components carried out using orthogonal vector projections
4	Stable paleomagnetic directions determined from principal component analysis
5	Data published completely as plots of VGP latitudes and/or of declination and inclination against stratigraphic position. The statistical parameters should be fully documented
6	Magnetic mineralogy determined
7	Field tests to constrain the age of magnetization undertaken where possible
8	A positive reversals test should be carried out
9	Radiometric ages, especially ⁴⁰ A/ ³⁹ Ar or U-Pb ages from volcanic ashes or bentonites, available in the stratigraphic section
10	Multiple overlapping sections confirm the polarity sequence

Paleontological dating of the limestones enabled correlation of major stage boundaries with the polarity sequence. The absolute ages of many stage boundaries are known independently, so the reversal pattern could be dated. Correlation with marine magnetic anomalies allowed the corresponding regions of the oceanic crust to be dated. The polarity sequence correlates well with the history of geomagnetic polarity derived from marine magnetic anomalies for chrons numbered 6C to 16 (Cande and Kent 1992).

Magnetozones in sediments can now be dated more accurately by means of cyclostratigraphy. This method is based on cyclical changes in the orientation of Earth’s rotation axis and the shape and orientation of its orbit. These are caused by the gravitational attractions of the Sun, Moon, and other planets (especially Jupiter). The changes (known as Milankovitch cycles) modify the insolation of the Earth and have long-term paleoclimatic effects on the deposition of sediments. They show as cyclical changes in color, bedding thickness, magnetic concentration, and isotopic ratios. The durations of the cycles are well known from astronomy, so by identifying and counting them they can be used to date a sedimentary section with greater accuracy. Cyclostratigraphy is an important dating method for determining the ages and durations of polarity zones in a magnetic polarity stratigraphy. Originally applied to Neogene sediments, the method has been extended to older Mesozoic rocks.

The correlation of dated polarity sequences from sections on land and in marine cores with the polarity record from oceanic magnetic anomalies is used to produce a geomagnetic polarity time-scale (GPTS). The record of geomagnetic polarity is well established from the present back to the Late Jurassic

Paleomagnetism, Principles, Fig. 7 Declination and inclination profiles in the Late Paleogene *Scaglia cinerea* formation, whose directions are shown in Fig. 4, correlated to the history of geomagnetic polarity derived from marine magnetic anomalies for chrons numbered 6C to 16

(Oxfordian), equivalent to the last 155 Million years of geological time. Three distinct episodes of reversal behavior are identified in this time interval. The oldest episode, comprising frequent reversals in the Late Jurassic and Early Cretaceous, is referred to as the M-sequence. The youngest episode, comprising the Late Cretaceous and Cenozoic, consists of frequent reversals known as the C-sequence. The M-sequence and C-sequence are separated by an interval, about 40 Ma in length, called the Cretaceous Normal Polarity Superchron (CNPS), in which correlated magnetic anomalies are absent.

The episodes of reversing behavior are long enough to make tentative interpretations about the reversal process. It is evident from the patterns of reversals that they are not periodic. Making allowance for the time spent in transition between opposite polarity states, statistical analysis indicates that the reversals in the C- and M-sequences occur randomly. The CNPS is interpreted as a time in which the Earth’s magnetic field did not reverse polarity. There are competing interpretations of why this should be. Whereas some investigators consider that the CNPS represents a special behavior of

the geodynamo, others regard it as an exceptionally long feature in a continuous reversal process.

The break-up of Pangea and the onset of sea-floor spreading date from the Early Jurassic, about 180 Million years ago. Between then and the earliest part of the marine polarity record, the corresponding regions of the ocean floor have low-amplitude magnetic anomalies but their confirmation in magnetostratigraphic records is fragmentary. For earlier eras, there is no marine polarity record to which a magnetic stratigraphy can be correlated. Despite this absence, a geomagnetic polarity time scale, dated by cyclostratigraphy, has been established for the Late Triassic and Early Jurassic (Kent et al. 2017). This was achieved by correlating magnetic stratigraphies in overlapping cores of continental sediments. The durations of magnetozones were dated by cyclostratigraphy, and the combined sequence was anchored by a radiometric age. The successful study indicates how a GPTS for earlier times may be established.

Environmental Magnetism

Paleomagnetism depends on the abilities of magnetic minerals to retain a stable magnetization for geologically long periods of time. The same properties make the minerals useful carriers of information about past environments and paleoclimates. They also enable investigations of present-day regional environmental pollution by heavy industry and

traffic, by using the concentrations of ferromagnetic minerals to trace heavy metal contamination.

Most environmental magnetic studies have been made in sedimentary archives. The magnetic susceptibility of a sediment reflects both the concentration and type of the magnetic minerals, whereas variations in grain size may be revealed in the stratigraphic variations of magnetic coercivity and remanent magnetizations produced in the laboratory. The proportion of an IRM carried by grains with coercivity above a certain value (the so-called S-ratio) can be an indicator of the relative size of the fine-grain fraction of the ferromagnetic grains. Lake sediments and wind-blown loess deposits have comparatively high deposition rates. Detailed evaluation of the magnetic signal in these sedimentary archives can reveal variations in environmental conditions during deposition. The magnetic properties of Chinese loess deposits illustrate the way in which magnetic parameters can act as proxy for paleoclimatic indicators.

The boundary between the Brunhes and Matuyama polarity chrons (age 780 ka), and the upper and lower boundaries of the Jaramillo normal polarity subchron (990 ka and 1070 ka, respectively), tie the loess section at Sanmenxia, China, to deep-sea sediments cored at Ocean Drilling Program Site 694 (Fig. 8). The wind-blown loess sediments in central China were deposited in cold climatic conditions. Paleosols formed under warmer, moister conditions that were conducive to enhancement of the magnetic susceptibility. Alternations of loess deposits and paleosols are

Paleomagnetism, Principles,

Fig. 8 Profiles of magnetic susceptibility (χ), hardness of remanent magnetization (S-ratio), and paleomagnetic polarity in a loess section at Sanmenxia, China, correlated to the marine oxygen-isotope ratio ($\delta^{18}\text{O}$) at ODP site 984. (Compiled from data in Wang et al. 2006). The peaks marked S1, S2, etc., correspond to paleosols; the lows between them are loess beds

accompanied by fluctuations in magnetic susceptibility, with low values marking the loess and higher values in the paleosols. Oxygen isotope results at the ODP site reveal cycles of climatic variation, which correlate well with the magnetic susceptibility and S-ratio data from the Sanmenxia section. The results demonstrate the usefulness of magnetic mineralogy parameters as proxies for isotopic data that document paleoclimatic variation.

Summary

Apart from isolated but important early pioneering studies, in which the characteristics of the geomagnetic field and the rudiments of rock magnetism were explored, paleomagnetism began to expand as a scientific discipline in the 1950s. As a result of the continuous development and refinement of instrumentation and analytic techniques, it has made many notable contributions to geological knowledge. Initially, it focused on the tectonic problem of “continental drift” and, by describing apparent polar wander paths for the different continents, it documented incontrovertibly the mobility of the continents. Matching of APW paths led to the reconstruction of supercontinents such as Rodinia, Pangea, Gondwana, etc. In parallel with this work, paleomagnetic analysis in conjunction with geological dating worked out the history of geomagnetic reversals. On the basis of the established reversal history and the rock magnetic properties of oceanic basalts, the hypothesis of sea-floor spreading was developed. This provided the key to the mechanism of plate tectonics. It allowed the documentation and dating of plate motions, and explained how “continental drift” took place. In turn, the pattern of magnetic reversals in the oceanic crust established a history of geomagnetic polarity for the past 155 Million years that has been confirmed by magnetostratigraphy and dated by radiometric, paleontological, and astrochronological methods. Paleomagnetism and rock magnetism have found wider application in addressing environmental problems and in contributing to an understanding of paleoclimatic history.

Paleoseismology

Shinji Toda
Disaster Prevention Research Institute, Kyoto University, Uji,
Kyoto, Japan

Synonyms

Earthquake archaeology; Earthquake geology

Definition

Paleoseismology An interdisciplinary field dealing with prehistoric or pre-instrumental earthquakes, in particular, their location, timing, and magnitude.

Introduction

Modern instrumental records of earthquakes cover only a little more than a century since 1890s (see ► [“Seismic Instrumentation”](#)). Historic accounts in several countries such as China, Japan, and Mediterranean regions allow us to extend the records of large earthquakes up to more than a couple of thousand years. However, for most parts of the globe, no earthquake data are available for the time periods of even the past hundreds to thousands of years that are comparable to repeat time of large earthquakes on a fault. Nevertheless, geologic sedimentary strata and geomorphic features preserve evidences for strong shaking, ground breaks, and landscape changes associated with large earthquakes. Although geologic and geomorphic records are incomplete and poorly constrained in time and space, they greatly help to understand faulting process and recurrence of earthquakes that are unavailable to seismologists due to the brevity of historic documents. We have defined this discipline as “paleoseismology” and such individual earthquakes are referred to as “paleoearthquakes.”

Paleoseismology is not a subbranch of seismology, but rather it is an interdisciplinary field of research, which borrows many concepts from structural geology and active tectonics. Methodology and techniques in paleoseismology are derived primarily from Quaternary geology and related disciplines such as geomorphology, soil mechanics, sedimentology, archaeology, paleoecology, photogrammetry, radioisotope dating or pedology (Grant 2007; McCalpin 2009).

The history of paleoseismology is as short as that of instrumental seismology. Although several pioneer geologists described surface faulting accompanying earthquakes in the late 1800s, geology and seismology at that time were separated (Yeats and Prentice 1996). But a few leading geologists, e.g., R. E. Wallace, C. R. Allen, and D. B. Slemmons, who studied San Andreas fault and active scarps in Nevada, and radiocarbon dating technique pervasive since about 1960s–1970s, played prominent roles in bridging the gulf between instrumental seismology and geology (Yeats and Prentice 1996). Since the 1970s, paleoseismic investigations have been yielding information about the paleo-movements on faults, dates of previous earthquakes, recurrence times, average slip rate, and earthquake effects over time intervals ranging from decades to thousands of years (Grant 2002). Consequently, numerous paleoseismic data (e.g., Sieh 1978) and fundamental concepts of recurrent large earthquakes (e.g., Schwartz and Coppersmith 1984) derived from field observations have largely contributed to progress in understanding the mechanics of earthquakes and faulting.

Unlike many subbranches of geology, the uniqueness of paleoseismology lies in its potential to decipher the future from the past and present. The traditional geological doctrine of “uniformitarianism,” which is used to reconstruct the past events from phenomena observable in the present, can be stretched to the future in paleoseismology to perform seismic hazard estimates and earthquake forecasting. The final goal and

major contribution of paleoseismology is to not only understand long-term faulting processes, but also to provide fundamental data and speculations to mitigate seismic hazard.

Paleoseismic Records

In seismology, estimation of earthquake magnitude depends on the performance of seismometers and on network coverage (see ► [“Seismological Networks”](#) and ► [“Statistical Seismology”](#)). Geomorphic markers, surface soil, and sediments are like poorly performing strong-motion seismograms. If an earthquake is large and shallow enough, the seismogenic faulting normally reaches the Earth’s surface. For inland intraplate and interplate earthquakes occurring shallower than ~20 km (“seismogenic layer,” see entries on ► [“Thermal Storage and Transport Properties of Rocks, I: Heat Capacity and Latent Heat”](#) and ► [“Thermal Storage and Transport Properties of Rocks, II: Thermal Conductivity and Diffusivity”](#)), $M \geq 6$ earthquakes may leave tectonic surface breaks and permanent ground offsets (Wells and Coppersmith 1994). The minimum magnitude of a paleoearthquake we can identify in strata and landscape is about $M \sim 6$ or higher (discussed later). For offshore earthquakes, including subduction associated mega-thrust events, $M \geq 7.5$ earthquakes leave records of significant coastal uplift and subsidence (e.g., Berryman et al. 1989). However, the paleoseismic record is spatially and temporally incomplete. Unlike instrumental seismology, recording processes by sedimentary layers are intermittent, and erosion often destroys the evidence for paleoearthquakes.

Fault Identification and Slip Rate

Identifying an active fault is the first step for paleoseismology. As described above, a large earthquake often leaves surface breaks and warping with significant offset when the faulting reaches the Earth’s surface. Detailed excavation studies often reveal evidence for each individual earthquake at an individual site. However, recognizing active traces relies on identification of geomorphic expression due to repetition of surface-faulting earthquakes as “fault landforms” for which deformation rate must be higher than local rates of erosion and deposition. Although the definition of “active fault” partly depends on the purposes (engineering or scientific) and on the usage of the terminology in different countries, it is usually identified by its association with tectonically deformed Quaternary-age materials or surfaces and by its potential to cause a large earthquake in near future.

To identify active faults and associated active landforms, aerial photographs and/or satellite images are commonly used (“aerial photographic interpretation”). High-resolution satellite images may be used to identify faulted landforms, even finding coseismic surface ruptures, around the globe, particularly in hardly accessible areas (e.g., Lin et al. 2006). The most frequently encountered feature is topographic lineaments. But lineaments are often developed by a combination of constructive geologic features and erosion. Therefore,

other characteristics associated with faulting such as triangular facets, fault scarps, sag ponds, and bulges should be found along a fault lineament (Fig. 1). Strike-slip faults accompany offset streams, shutter ridges, beheaded streams, wind gaps, and offset terrace risers. Multiple and systematic fault landforms along a single trace increase the reliability of its identification as an active fault trace. Most of such traces tend to be roughly along geologic faults juxtaposing different geologic units so that a traditional geologic reconnaissance is also useful to constrain an active fault zone. Fresh fault gouge (clay) and/or fault breccia are often exposed on outcrop along geomorphic traces. Geologic drilling and shallow coring are auxiliary approaches to constrain the location of a fault trace and sometimes help to estimate vertical offsets of stratigraphic units, particularly much deeper than trench excavation (e.g., Dolan et al. 2003). Deeper geologic information down to a few kilometers depth from industry oil wells provides a larger picture of fault structure and associated folds (e.g., Tsutsumi and Yeats 1999). Several other methods reveal subsurface geologic structures for the areas having shallow water table and urban areas with limited open space. For example, cone penetrometer testing (CPT) and large diameter borings can be applied for these conditions (Grant et al. 1997). The “Geoslicer” (Nakata and Shimazaki 1997), which consists of a sample tray and a shutter plate, can be inserted into the ground by a weighted vibrator to extract a sliced soil sample of larger than a few meters dimension (Takada and Atwater 2004). Geoslicer can directly sample a fault itself without losing information of strike, dip, and geologic context of the fault.

Spatial resolution and accuracy in aerial photographic images are limited. Recently, airborne Light Detection And Ranging (LiDAR) surveys, which measure bare topography irradiating a laser beam from an airplane or helicopter, have been widely used to image very detailed fault-zone topography beneath dense vegetation cover (e.g., Sherrod et al. 2004) and urbanized areas (e.g., Kondo et al. 2008). These data are at the appropriate scale (meters) and accuracy (decimeter) to provide useful measurements of the fine features of fault landforms (Arrowsmith and Zielke 2009). Airborne Laser Swath Mapping (ALSM) is also expected to find hidden active faults.

To locate an active fault trace and to confirm deformed subsurface structure various geophysical imaging techniques such as seismic reflection and refraction, ground-penetrating radar (GPR), aeromagnetic surveys, and gravity surveys are employed. The advantage of these techniques is that these are nondestructive methods for seeking deeper structures (Bond et al. 2007). Highresolution seismic reflection surveys are most pervasive to visualize shallow geologic structure associated with details of fault activity, even to reveal blind fault and fault-related fold (Fig. 2).

These geomorphic, geologic, and geophysical explorations for fault identification also provide information about long-term slip rates. The slip rate on a fault, S , is calculated by dividing cumulative displacement (D) across the fault by time interval T (Fig. 3),

$$S = D/T. \quad (1)$$

tectonic bulge; F, fault saddle; G, graben; H, offset stream; I, shutter ridge; J, beheaded stream; K, wind gap; L-L', offset of piedmont line; M-M', offset of terrace edge; Q, fault pond

Paleoseismology, Fig. 2 An example of fault-related fold revealed by a seismic reflection survey. Depth-converted P-wave seismic reflection profile across two flexures in south Osaka, Japan (Sugiyama et al. 2003). The strata are composed of Plio-Pleistocene non-marine and marine sediments

To obtain S , we need to find “piercing lines” or “piercing points” which intersect a fault zone as a line or a point. The piercing lines and points should be formed before the subsequent faulting events occurred. Geomorphologically, offset ridges, streams, and gullies become piercing lines, but more often well-reconstructed and dateable terraces and terrace risers are employed as the best piercing lines to estimate slip rates (e.g., L-L', M-M', M1-M1' in Fig. 1). If offsets increase with terrace ages, the fault is considered to have been continuously active. Offset bedrock geology is also used as piercing lines and points to roughly estimate the very long-term slip rate. Cultural features such as roads, fences, walls, buried pipes, and rice paddy boundaries across a fault line are often used to measure the amount of coseismic slip for very recent earthquakes and historic events. In coastal and fluvial areas, where uplifted terraces are commonly seen, the vertical component of the slip rate S , is more easily obtained than the lateral component. Such slip rate estimates are used for classifying the fault activity (e.g., in Japan, class A: order of m/1,000 years; class B: order of 0.1 m/1,000 years; class C: order of 0.01 m/1,000 years), which is an important index for the estimation of the recurrence time of major earthquakes or for future seismic activity (Research Group for Active Faults of Japan 1992).

Evidence for Paleoearthquake

Paleoseismic evidence is either primary or secondary (McCalpin 2009). Primary evidence is formed by tectonic deformation resulting from coseismic slip along a source fault plane. Secondary evidence is produced by earthquake shaking. Paleoseismic features are also distinguished as being on or above fault trace (on-fault or near-field features), or

away from or far above a fault trace (off-fault or far-field features) (McCalpin 2009). Because off-fault evidence for a paleoearthquake is mostly associated with strong shaking, the problem with the off-fault evidence is its difficulty in finding the corresponding seismic source. Thus, the majority of paleoseismic studies focus only on “on-fault” evidence.

Encountering a natural exposure of faulted young sediment is extremely rare. We thus excavate trenches across a fault zone (sometimes parallel to the fault zone) to expose faults and young strata that record evidence of paleoearthquakes. The site for trenches is chosen based on the fault location, land usage, sediments preservation, paleoearthquake records, and abundant dating material. The best trench site is considered as the one where: (1) deformation zone is narrow, or fault strand is single and representative of the entire fault zone; (2) frequent but dilute sedimentation processes occur with numerous dateable materials. The trench walls are not long-lived exposures and mostly not reproducible so that detailed observations and objective records by as many observers as possible are required (Grant 2007). A trench log, which is a geologic sketch, is used for defining and mapping sedimentary units and recording evidence for surface-rupturing earthquakes, which we call an “event horizon.”

An event horizon is used as the ground surface at the time of a paleoearthquake (Pantosti et al. 1993). The event horizon may be preserved as scarp-derived colluvial wedge deposits, unconformities that terminate faults, and warping (Fig. 4), each of which is defined as an “event indicator” (Scharer et al. 2007). It is most likely to conclude that surface rupture and significant deformation such as folding and tilting along active traces are the direct products of seismogenic faulting.

Paleoseismology, Fig. 3 (a) Schematic diagram showing the cumulative displacement (D) at a site along a fault as a function of time (T). D_{co} coseismic displacement, T_r recurrence interval, T_e elapsed time since the most recent earthquake, S slip rate estimated from D/T . (b) Time-predictable model. (c) Slip predictable model. (After Shimazaki and Nakata 1980)

There are various kinds of evidences for paleoearthquakes which can be rated for their reliability.

Upward fault termination: This is the most common and easily identified event indicator in which faults and faulted strata are overlain by a non-deformed horizon (Fig. 4a). But one tends to misinterpret an event horizon in special situations where fault slip near the ground surface tapers and dies out upward (Bonilla and Lienkaemper 1990). Thus the quality and confidence level of this indicator depend on the amount of slip and stratigraphic conditions between different exposures at a site.

Fissure fills: Fissures and fissure fills are a sort of open crack associated with faulting and younger material filled during postseismic process (Fig. 4b). They are commonly seen as a wide zone of alternating tension gashes and compressional mole tracks immediately after a large surface-rupturing earthquake due to strike-slip faulting.

Colluvial wedge: The colluvial wedge is formed on the footwall side as a result of collapse of the fault scarp exposed at the time of a scarp-forming earthquake (Fig. 4c, d). A trench wall across a fault normally exposes a wedge-shaped section tapering toward or away from the fault scarp, often showing upward-coarsening structure, similar to talus deposition. When a bedrock fault plane is exposed at the earthquake, the collapsed sequence of gouge, breccia, and intact bedrock block are sequentially observed in the wedge. When it occurs within the loose sediments, scarp degradation is involved. Colluvial wedges are not only seen along normal faults but also along strike-slip and thrust faults.

Angular unconformity associated with tilted and folded strata: An angular unconformity is produced by broad deformation of subsurface sediments due to faulting and subsequent erosion and sedimentation (Fig. 4e, f). If a fault plane is simple and it is hard to find an upward termination, angular unconformity would be a substitutive criterion to identify an event horizon. But, except for significant inclination of strata, horizontal sedimentation must be guaranteed. Adhesive composition with clay and silt often shows a veneer deposit along a slope, which often mimics crustal deformation.

Minor cracks and faults associated with subtle deformation: Where the amount of displacement is small, and/or surface condition is dry, numerous minor cracks or tension fissures associated with deformation can be produced (Fig. 4g, h).

The deeper we expose stratigraphic units, the more events and associated structures are likely to be exposed. Since evidence associated with older events tends to be destroyed and obscured by the most recent event, we must restore the stratigraphy and structures prior to the most recent event and then reinterpret the older events to identify multiple paleoearthquakes at a site (“Retrodeformation analysis,” McCalpin 2009). It means that reliability of the paleoearthquake tends to be reduced when we go farther back in the past. To have higher confidence for a paleoearthquake, multiple exposures of a fault and/or significant deformation (event indicators) in the same stratigraphic horizon should be confirmed at a site (Scharer et al. 2007).

Time Constraints of Paleoearthquakes

Although there are several methods to directly determine ages of fault activities from fault gouges (e.g., Fukuchi 2001), timing of each paleoearthquake is commonly constrained by ages of deformed stratigraphic units and overlying undeformed strata, for which many dating approaches using different isotopes have been used (see details in Grant 2002 and references therein).

Among them, radiocarbon dating is the most powerful and pervasive technique in paleoseismic studies. In this technique, the time since the death of a plant or animal is estimated by measuring the sample’s residual ^{14}C content relative to modern standards and the half-life decay constant of ^{14}C .

Paleoseismology, Fig. 4 Schematic diagrams of typical stratigraphic event indicators of paleoearthquakes in both on-fault and off-fault regions. Solid triangle beside each panel indicates an event horizon. Several on-fault diagrams are based on Allen (1986) and Okada

(1991). Note that confidence level of paleoearthquakes increases from the diagrams in off-fault regions to the ones showing direct fault exposure

(5,568 years). The beta particle counting method conventionally requires 2–200 g of carbon and allows us to date back to ~40,000 years before present (yBP; actually years before 1950 AD). Meanwhile, newly developed Accelerator Mass Spectrometry (AMS) dating requires samples as small as a few milligrams and extends the measurable date back to 50,000–60,000 yBP. Since the ratio of ^{14}C to ^{12}C has varied with time due to variations in number of cosmic rays associated with the strength of the Earth's magnetic shield, measured radiocarbon age needs to be converted to calendar date. From dendrochronological approaches with tree rings, glacial varves, corals that annually record the amount of ^{14}C in the atmosphere, radiocarbon ages are calibrated to corresponding

calendar dates back to about 24,000 years before present (Stuiver et al. 1998).

Such dendrochronological approaches to constrain timing of a paleoearthquake have been commonly employed since Jacoby (1989). Time constraint of a paleoearthquake requires at least two radiocarbon dates that bracket an event horizon, in which probabilistic density is calculated from the calibrated dates of both samples. To have better constraints for paleoearthquakes, there are several calibration programs, one of which “OxCal” (Bronk Ramsey 2001; Lienkaemper and Bronk Ramsey 2009) not only calibrates the radiocarbon ages to the calendar years but also implements rigorous means of estimating these event ages and their uncertainties using Bayesian statistics.

As mentioned before, several countries have historical accounts longer than a thousand years or more and thus may cover more than a few seismic cycles of very active faults. However, the longer we go back in the past, the fewer and less reliable the historical accounts are. In addition, most of the historical earthquakes roughly control isoseismal areas from documents of earthquake damage, but not the specific source of each earthquake. Thus a combination of such historical documents and paleoseismic evidence with well-determined dates are used to confirm the source fault for such historical earthquakes (e.g., Armijo et al. 2005).

Archaeoseismology reaches further back in the past to reveal prehistoric earthquakes based on their effects on man-made objects, usually buildings or other monuments (Karcz and Kafri 1978, see entry on ► “Earthquake, Archaeoseismology”). The time range depends on history and archaeology in each country. Historic accounts are often available and tied with ruins due to devastating shaking, paleo-liquefactions, and paleo-landslides (rock-slides) at archaeological sites. The advantage of archaeoseismology is narrow time constraints of earthquake occurrence by archaeological and historical knowledge. Characteristic off-fault damage types include horizontal shifting of large building blocks, downward sliding of one or several blocks from masoned arches, collapse of heavy, stably-built walls, chipping of corners of building blocks, and aligned falling of walls and columns (Marco 2008). In some rare cases, faults intersect with archaeological sites, which enables us to measure sense and size of slip and constrain its occurrence time. Several recent archaeoseismological studies in the Eastern Mediterranean region in particular have been unveiling the detailed slip history and rupture behavior of the Dead Sea fault (e.g., Meghraoui et al. 2003), and large earthquakes associated with mythology along the Aegean Extensional province, Cyprus, and Hellenic Arcs (e.g., Stiros 2001).

Magnitude and Frequency of Paleoearthquakes

Like “uniformitarianism,” no paleoearthquakes can be inferred without detailed knowledge of recent observed earthquakes that left important clues between subsurface seismic processes and surface deformation. Since paleoseismology relies on paleo-surface information preserved in geology and landforms, seismic and geologic data compilations of recent large shocks associated with surface-ruptures, tilt, warping, and other earthquake-related deformation are necessary.

As seismologists found simple self-similar scaling laws for source faults, dimension and magnitude, surface ruptures compiled from worldwide data have similar scaling relations (Wells and Coppersmith 1994). For example, the empirical relation between surface rupture length (L in km) and magnitude (M) is expressed as $M = 5.16 + 1.12 \log L$ for strike-slip fault. For seismic hazard assessment, such an empirical relation is increasingly applied to estimate magnitude from the

length of an identified fault trace. Similar empirical scaling relations are found between coseismic surface displacement and magnitude. For maximum displacement $D_{\max}$ in meter, $M = 6.69 + 0.74 \log D_{\max}$. For average displacement, D_{ave} in meters, $M = 6.93 + 0.82 \log D_{\text{ave}}$. Besides fault length, coseismic slip, either $D_{\max}$ or D_{ave} , is also increasingly used to estimate the magnitude of a paleoearthquake. There are two ways to have such coseismic slip from paleoseismic data. One gives an indirect estimate from slip rate (S) and average recurrence interval (T_r) of paleoearthquakes along a fault as $D = S \times T_r$. The other provides direct measurement from vertical separation of faulted strata on trench walls in particular for reverse faults and three-dimensional reconstruction of lateral offset of piercing points for strike-slip faults.

In terms of magnitude and frequency estimates for an active fault, one of the greatest impacts of geology on seismology is the “characteristic earthquake model” (Schwartz and Coppersmith 1984, see entry on ► “Characteristic Earthquakes and Seismic Gaps”). This model illustrates the concept of the repetitions of similar size of large earthquakes with a similar amount of slip, rupture length, and magnitude along a fault. The model also emphasizes that paleoseismic records from a fault suggest more frequent occurrence of large earthquakes compared to the ones extrapolated from the Gutenberg–Richter relation of regional seismicity (Wesnousky 1994). If only scanty paleoseismic information on a fault is available, one simply uses the characteristic earthquake model to estimate the size of earthquakes potentially caused by the fault.

If the characteristic earthquakes on a fault occur periodically or quasi-periodically with characteristic slip, we would not have any difficulty to approximately forecast the time and magnitude for the next large earthquake (Fig. 3a). However, as summarized below, most of the recurrences of earthquakes are not periodic and may be influenced by recent rupture history. Regarding the slifetime relation at a site along a fault, under the assumption of constant long-term slip rate, two conceptual models are proposed (Shimazaki and Nakata 1980). The “time-predictable model” can predict the time of the next earthquake from a knowledge of the previous slip (Fig. 3b), whereas “slip predictable model” cannot predict the time but amount of slip, taking the slip deficit since the last one into account (Fig. 3c). In reality, however, at least 30 prehistoric earthquakes in a 6000-year-long record at Wrightwood along the San Andreas fault, southern California, follow neither time-predictable nor slip-predictable model (Weldon et al. 2004). The paleoseismic history might prove that slip occurs at a wide range of stress levels and does not return to the same postseismic stress level, keeping quasi-periodic recurrence behaviors (Scharer et al. 2010).

To furnish the magnitude estimate using the length of a fault, one must define the extent of a fault. In nature, we rarely encounter an isolated long single fault trace. Instead, we more often map a group of faults or a network of faults, which require

us to define each seismogenic fault. To subdivide faults into portions, the concept of “fault segmentation” is employed. “Fault segment” is a general term for the portions of a fault or fault system or fault zone. There are several types of fault segments ordered in terms of earthquake occurrence; *earthquake segment*, *behavioral segment*, *structural segment*, *geologic segment*, and *geometric segment* (McCalpin 2009). Identifying and defining earthquake segments that directly determine the size of earthquakes is the ultimate goal. However, numerous studies started to focus on changes in fault orientation and boundaries of fault traces (branches, intersections, separations, and step-overs) to identify each structural and geometric fault segment. There are also varieties of scale of segment and “discontinuous gaps.” But since we assess seismogenic fault, kilometer-scale traces are generally taken into account. To identify each seismogenic fault among many complex mapped fault traces, “5-km separation criteria” are now broadly employed for the hazard assessment (e.g., Earthquake Research Committee in Japan (ERC), 2005). Several studies done in the late 1980s and early 1990s compiled the surface ruptures, associated historic earthquakes, and mapped active traces around the globe and then concluded that rupture propagation beyond the 5-km step width is highly unlikely (Barka and Kadinsky-Cade 1988; Wesnousky 1988, 2006). Although these should be case-dependent with many factors, “5 km” is still a standard separation distance to identify each seismogenic fault segment.

A long continuous fault (system) cannot be simply divided by the 5-km separation criterion instead. It generates a variety of rupture patterns and sizes of earthquakes. Several conceptual models are proposed with slip rates and event age constraints at several sites along a single fault or a single fault system. The characteristic earthquake model is one of the several conceptual models. In reality, a space-time diagram of fault rupture patterns estimated from intensive paleoseismic surveys is not so simple to apply the conceptual model. Detailed examples from the southern San Andreas fault (Fig. 5, Weldon et al. 2004) and the North Anatolian fault, Turkey (Hartleb et al. 2003) show the complicated rupture patterns on a fault system.

Off-Fault Paleoseismology

Although a limitation of off-fault evidence is its difficulty in identifying the seismic source, it becomes supportive evidence for paleoearthquakes, together with on-fault evidence. There are mainly two types of off-fault evidence for paleoearthquakes: one is due to strong shaking, and the other is related to features associated with broadly distributed coseismic and postseismic deformation (see ► “Earthquakes and Crustal Deformation”). The former triggers liquefaction, terrestrial and submarine landslides, and tsunamis. The latter leaves uplifted, tilted, and subsided ground surfaces recorded on shorelines and marine and river terraces, where paleo-altitude can be estimated and a flat surface is guaranteed.

Besides on-fault geology and geomorphology, preservation of such paleoseismic evidence is necessary. In addition, synchronicity and spatial extent of off-fault events are keys to distinguish paleoearthquakes from other causes of such secondary geologic features.

Liquefaction and associated features such as sand blows, sand boils, sand volcanoes, lateral spreading, clastic dikes, hydraulic fracturing, and rarely gravel blows and gravel dikes are the products of strong ground acceleration due to a large earthquake. Worldwide data on historical earthquakes show that the features having a liquefaction origin can be developed at earthquake magnitudes as low as about 5, but that a magnitude of about 5.5–6 is the lower limit at which liquefaction effects become relatively common (Ambraseys 1988; Obermeier 2009). Therefore, paleo-liquefaction is strong evidence for large earthquakes in the past. Although it is difficult to excavate trenches or pits targeted only for paleo-liquefaction, we often encounter evidence for paleo-liquefaction at archaeological sites, which can constrain the earthquake occurrence time much better than ^{14}C date due to cover-up by the non-damaged younger ruins and horizons (e.g., Fig. 6, Sangawa 2010). Since liquefaction can be commonly repeated at the same site where the recent large earthquake occurred, we can sometimes find the paleo-liquefaction on trench walls and confirm the recurrence of strong shaking at the site (e.g., Wesnousky and Leffler 1992).

Strong ground motions in mountainous regions often trigger slope failures. In the regions characterized by steep unstable topography, we can identify massive landslides and scarps occurred in the past in aerial photographs. However, interpreting an earthquake-induced landslide or group of landslides excluding other factors like heavy rainfall is particularly hard, and levels of confidence in the resulting interpretation vary widely. Comprehensive geologic surveys with dating of landslides and several criteria (Jibson 2009) that discriminate landslides from other factors are required.

Widespread thin sediments in coastal regions reveal occurrence of paleo-tsunamis. Sand layer often containing pebble and shell deposit is extensively deposited by tsunami waves and its inundation on the coastal areas (see ► “Tsunami”). Although there is no single convenient feature to distinguish tsunami deposits from those generated by other events, sedimentary facies analysis with several key features is indispensable for identifying tsunami deposit (Shiki et al. 2008). To better identify paleo-tsunami deposits, there are limited conditions to preserve such sand layers; paleo-tsunami deposits are distinguished from black humus and mud deposits if the paleo-tsunami reaches the areas in swales, marsh and other calm environments where no sand sources can normally flow. Numerous studies, which employed shallow coring, pits, and trenches, exposed tsunami sand sheets intervened by finer and datable organic soils (e.g., Atwater 1987). The recent significant contribution of the tsunami deposit studies to the subduction process is to find prehistoric M9 class earthquakes

Paleoseismology, Fig. 5 Two possible rupture sequences on the southern San Andreas fault (Weldon et al. 2004). Vertical grey bars are ranges in age for earthquakes at the sites listed at the lower margin and

horizontal bars are rupture lengths. Open boxes represent multiple events age ranges; the individual event ages are unknown. Grey shading indicates regions and times with no data

Paleoseismology, Fig. 6 History of mega-thrust earthquakes along the Nankai trough, Japan (Sangawa 2010). The subduction zone is divided into five rupture segments A–E (F is the source of 1923 $M = 7.9$ Kanto earthquake along the Sagami trough). The horizontal lines with number in lower panel indicate the rupture extents and occurrence years of large earthquakes. Dots with number denote archaeological sites with exposed significant liquefactions at specific ruins and their calendar years. Recent archaeo-seismological data filled gaps in long recurrence intervals originally estimated by only historic accounts (e.g., possible rupture on A and B segments at the 1,498 earthquake), and making the Nankai subduction earthquake cycles more regular and frequent. Tsunami deposits recovered from coastal lakes, lagoons, swamps, and lowlands are also filling the gaps (e.g., Takada et al. 2002) and also provide much longer rupture history back to the entire Holocene period (Komatsubara and Fujiwara 2007)

and their recurrence intervals along the 2004 Sumatra-Andaman (Jankaew et al. 2008), and along the Kuril trench (Nanayama et al. 2003), and relation with the M8 class predecessors of the 1960 M9.5 Chile earthquake (Cisternas et al. 2005), which breaks through the conventional idea on regular

occurrences of subduction earthquakes (see ► “Great Earthquakes”).

Besides paleo-tsunami deposits, submarine turbidites are another geologic clue to reveal large submarine and coastal earthquakes. Goldfinger et al. (2007) demonstrated their validity and significance of sediments associated with earthquake-triggered turbidity currents by analyzing numerous piston cores collected from submarine channels and canyon systems draining the northern California continental margin. By studying synchronous triggering of the turbidity currents, they found 15 turbidites during the last ~2,800 years, equivalent to an average repeat time of ~200 years which is similar to the onshore value of ~230 years along the northern San Andreas fault. Along-strike correlation also suggests the ~320-km rupture extent of the most of the younger events.

Broad deformation of off-fault areas is another indicator for paleoearthquakes (see ► “Earthquakes and Crustal Deformation”). Vertical deformation can induce changes in local rates of deposition and erosion that provide evidence of a paleoearthquake, particularly in fluvial and coastal environment (McCalpin and Carver 2009). Subduction associated mega-thrust earthquakes and dip-slip intraplate earthquakes largely change horizontal markers such as shorelines prior to an earthquake and record off-fault coseismic uplift (e.g., Meghraoui et al. 2004) which are preserved as uplifted terraces and shorelines. Coastal areas facing subduction zones, such as southwest Japan, Taiwan, New Zealand, and Crete in Greece, have several steps of elevated terraces and shorelines associated with the mega-thrust earthquakes (see ► “Seismicity, Subduction Zone”). But significant coseismic uplifts are also inferred to have been formed by shallow near-coast offshore active faults that might be branched from subduction interface (e.g., Maemoku 2001). Although dating paleo-marine terraces and shorelines is not easy, coral reefs, coral microatolls (e.g., Zachariasen et al. 1999), fossils of sessile organisms inhabit intertidal level and become both paleo-shoreline markers and indicators of timing of earthquake occurrences. For older terraces over 50 ka, other dating techniques and regional tephra fallouts are used to estimate the emergent dates. In Japan, altitudes of uplifted marine terraces formed at marine oxygen isotope stage 5e (~120 ka) often provide us with the best estimates of long-term uplift rates associated with interplate events (Koide and Machida 2001). In contrast to coseismic uplift, studies for paleoseismic subsidence are much fewer. Subsidence associated with a subduction earthquake normally occurs inland from the rebounded uplift zone. Here, buried soil of subsided marsh and forest records the sudden vertical deformation (e.g., Atwater et al. 1995).

Permanent deformation of landscapes associated with seismogenic faulting is sometimes modified or amplified by postseismic crustal movement. Recent mega-thrust subduction events caused not only coseismic uplift, but also postseismic transient deformation that lasts more than a few decades (see

► “Earthquakes and Crustal Deformation”). Although contribution of postseismic deformation associated with paleoearthquakes is hardly measured in the uplifted terraces, Sawai et al. (2004) used fossil diatom assemblages to infer the gradual changes in sedimentary environments corresponding to the transient postseismic deep creep that occurred in the seventeenth century along the Kuril subduction zone.

Seismic Hazard Assessment Based on Paleoseismology

Paleoseismic data are directly used for making probabilistic seismic hazard maps (see ► “Seismic Hazard”) which incorporate information on fault location, dimension, geometry, largest earthquake from such dimension, slip rates, and recurrence intervals (e.g., Working Group on California Earthquake Probabilities 1995). Two types of statistical models of earthquake occurrence are commonly used to estimate earthquake probability: a stationary Poisson model and a conditional quasi-periodic model (see ► “Statistical Seismology”). The former is used for active faults or active seismic regions where only frequency of large earthquakes is available. The latter considers fluctuations of repeat times (coefficient of variation in recurrence time) and elapsed time since the most recent event (see Fig. 3), which is time-dependent and compatible with the strain accumulation process. Several probability density functions such as normal, lognormal, Weibull, or gamma distributions are used for the recurrence process. Among them, the Brownian Passage Time function (Matthews et al. 2002) is evaluated as so far the best function because of its capability to account for the stress perturbations and has been adopted for the probabilistic seismic hazard studies in California and Japan (Field et al. 2009; ERC 2005). Time-dependent seismic hazard considering conditional probabilities on most major active faults provides us with more realistic estimates (Fujiwara et al. 2009).

If further detailed paleoseismic information is available for a specific fault, a “scenario earthquake model (seismic hazard maps for specified seismic sources)” is often proposed to show the strong shaking for the areas being assessed when the specific earthquake occurs (ERC 2005). When providing paleoseismic data to seismic engineers, possible rupture patterns for the next earthquake, slip distribution, and plausible locations of asperities becomes additional information (Somerville et al. 1999).

In addition to the shaking damage, surface rupture and displacement associated with a large earthquake often destroy man-made structures. Structures for human occupancy (e.g., hospital and school) and critical buildings (e.g., nuclear power plant) can be so located to avoid the traces of active faults (e.g., the Alquist-Priolo Earthquake Fault Zoning Act in California, see entry on ► “Seismic Zonation”). To mitigate direct damage due to surface-faulting, detailed positions of active faults and their paleoseismological properties are progressively been opened to the public through the internet.

Issues in Paleoseismology and Perspectives

There are fundamental limitations of the geologic approach to infer paleoearthquakes in time and space. The following are major caveats in using paleoseismological information:

1. Surface ruptures are commonly associated with $M > 6$ earthquakes (Wells and Coppersmith 1994) that occur at shallow depths (mostly < 20 km), even though $M \sim 5$ earthquakes may also leave surface ruptures in the case of extremely shallow hypocenter (< 5 km) and volcanic environments (Payne et al. 2009, see entry on ► “Earthquakes, Volcanogenic”). However, we must know that geomorphic and stratigraphic evidence for all $M > 6$ paleoearthquakes is not always produced. It totally depends on regional tectonic setting, depth of hypocenter (thickness of seismogenic crust), fault slip sense, and surface geologic conditions. For example, revisiting the inland earthquakes in Japan since 1923, no more than half of the $M \sim 7$ earthquakes left the surface breaks comparable to the seismic faults, which obviously underestimates the probabilities of even $M \sim 7$ shocks (Toda and Awata 2008). Even along major strike-slip faults, we experienced enigmatic large earthquakes that did not leave clear surface rupture (e.g., 1989 Loma Prieta earthquake and 2010 Haiti earthquake).
2. Rates of erosion and sedimentation at regional and local scales control preservations of fault landforms and evidence for paleoearthquakes at excavation sites. Human destruction of the surface geology and topography due to urbanization or farming often destroys evidence of very recent paleoseismic events. Furthermore, obtaining better time constraints for paleoearthquakes is rare due to the lack of abundant dating material.
3. Geologic and topographic evidence normally includes interpretation with epistemic uncertainties. Complete agreement is rare in aerial photographic interpretation. “Trench parties” (Grant 2007) often create indecisive debate that is not visible in the final publication in which simple trench logs are only illustrated. Photos and detailed sketches are objective records, but they are infrequently opened to the public and are hardly accessible. Therefore one should be aware that publications often underestimate or overestimate numbers of paleoearthquakes and need extra effort to clarify quality measurements and other paleoseismic interpretations.
4. Paleoseismic study cannot precisely reveal rupture extent, thus magnitude of an earthquake without any help of historic accounts. Space-time diagrams of paleoseismic events on a fault or fault system may only conclude the cases adjacent segments did not simultaneously rupture through. Displacement data of a paleoearthquake would be useful information to estimate magnitude based on the empirical scaling law (Wells and Coppersmith 1994). But at least five to ten measurements are stochastically required

to characterize magnitude of a paleoearthquake (Hemphill-Haley and Weldon II 1999).

5. Although we simply apply the characteristic earthquake model or extended segmentation model under the elastic rebound framework (see ► “Earthquakes and Crustal Deformation”), there may be intrinsic uncertainties of repeated faulting processes, for example, nonlinear strain accumulation and complex rupture process. This might be a subject seismologists have to reveal. But paleoseismology instead can be suggestive with data that also conquer “uniformitarianism.” For example, the 2004 $M = 9.2$ Sumatra-Andaman earthquake was an extraordinary earthquake which can be hardly expected from historic accounts. However, intensive detailed studies about coral microatolls (Zachariasen et al. 1999) and tsunami deposits (Jankaew et al. 2008) suggested there were frequent huge events in the past, even if we do not see them in historic ages. This is an important role of paleoseismology.

Summary

Paleoseismology, which is the study of prehistoric or pre-instrumental earthquakes, is an interdisciplinary field of research mainly encompassing seismology, geology and geomorphology. Starting from identifying active faults, various field and laboratory techniques such as aerial photography interpretation, trench excavation, and radiocarbon dating are used to reveal the spatial extent and occurrence times of paleoearthquakes, and associated long-term movements of active faults. Evidence for paleoearthquakes is not only preserved in strata across a fault but also found far from the source as paleo-liquefaction, paleo-landslide, and paleo-tsunami deposits. Empirical relations between rupture length and slip versus earthquake magnitude from recent instrumentally recorded shocks enable us to estimate the size of future earthquakes on a fault or fault zone. Detailed rupture history of a fault also allows us to estimate time-dependent probabilistic seismic hazard. Although there are fundamental limitations and incompleteness in field data, contribution of paleoseismology in understanding the long-term faulting process is enormous and indispensable. Recent progress in paleoseismic data accumulations also allows seismologists and seismic engineers to make better seismic hazard maps to mitigate seismic damage in the future.

Definition

Plate motions: horizontal piecewise movements of Earth's outer shell that occur over million years time scales and that can be measured or inferred from a range of geophysical techniques.

Introduction

Plate tectonics is a remarkable theory. Its central tenet, which is widely known, states that the surface of the Earth moves in a piecewise coherent fashion via a number of rigid plates (Wilson 1965; Morgan 1968), with most of the deformation focused along plate boundaries (Stein 1987). The underlying dynamic mechanism responsible for plate motions has been long identified in lateral buoyancy variations within the Earth mantle (Forte 2010). However, 40 years after the acceptance of plate tectonics, the details of how these forces may vary in time to modify plate movements remain limited, and we still fail to answer basic questions of fundamental importance: *Why do plates change their motions as shown by the geologic and geodetic records? – What are the spatial and temporal patterns of forces responsible for such changes?* The main difficulty stems from our poor knowledge of the *force balance* in plate tectonics. It is widely agreed that plate motions are driven by convection in the Earth's mantle (Hager and O'Connell 1981; Davies and Richards 1992). But the influence of other driving and resisting mechanisms, especially along plate margins, remains unclear. Forces concentrated along plate margins are known as plate boundary forces (Forsyth and Uyeda 1975) and it is likely that they play an important role in modulating plate motions (Humphreys and Coblenz 2007).

Portions of this entry, including all figures, were previously published in Iaffaldano, G., Bunge, H.-P., 2009 – Relating rapid plate-motion variations to plate-boundary forces in global coupled models of the mantle/lithosphere system: Effects of topography and friction, *Tectonophysics* v. 474, pp. 393–404 – and are reprinted here with permission of Elsevier.

A key component of plate boundary forces is the gravitational collapse associated with large mountain belts extending along plate margins. Climate-induced variations in topography, related to uplift and erosion in orogens, have been long recognized as possible controls in tectonics (Koeppen and Wegener 1924), and may therefore be capable of initiating variations in plate motion on regional and global scales. Conversely, geodynamicists can use inferences on topography and plate motion variations as powerful probes into the underlying force balance of plate tectonics.

Temporal variations in plate motions provide significant constraints on the budget of forces acting upon plates. This is because, by virtue of Newton's first law of motion, any change in plate motion is necessarily driven by variations in one or more driving or resisting forces. With the advent of space geodetic techniques (Dixon 1991), increasingly accurate estimates of global plate motions and their temporal variations are now available (Sella et al. 2002). While geodesy measures the current rates of plate motion, one can also glean long-term constraints on plate motion from paleomagnetic observations derived from the magnetic isochron record of the ocean floor. In fact, recent paleomagnetic plate motion models approach temporal resolutions on the order of 1–2 Myrs and reveal a number of rapid *velocity-changes* (few cm/year) occurring over time periods of a few Myrs or less (Müller et al. 2008). Some of these are particularly evident in the Southern Atlantic (Fig. 1a) and in the Indian Ocean (Fig. 1b). Their short duration makes it unlikely to attribute the changes to variations in the internal distribution of mantle buoyancies. In fact, these evolve globally on longer time

scales on the order of 50–100 Myrs (Bunge et al. 1998), although locally changes may occur over some 10 Myrs (Forte et al. 2009). It is reasonable to link these rapid changes to variations in plate boundary forces.

Plate Tectonics and the Rheology of the Lithosphere

The regime of plate tectonics requires high strain rates and low resistive stresses to coexist simultaneously along plate margins. But it is challenging to model this regime on a computer, because it is difficult to simulate shear failure along plate boundaries. To overcome this challenge, some models of the lithosphere incorporate highly non-Newtonian, viscous creep, strain-rate weakening rheologies together with viscoplastic yielding. Moresi and Solomatov (1998) explored the effects of temperature-dependent viscosity in combination with a plastic yield stress: The former causes the cold upper boundary layer (lithosphere) to be strong, while the latter allows the boundary layer to fail locally in regions of high stress. The success, measured through a so-called *plateness*, is evident when extreme strain-softening rheologies, known as pseudo-stick-slip (Bercovici 1995), are employed (Bercovici 2003). Unfortunately, the rheological parameters required for pseudo-stick-slip agree poorly with laboratory experiments of ductile deformation performed on olivine (Kirby 1983), particularly at the pressure and temperature conditions typical of the upper mantle (Karato and Jung 2003). Figure 2 shows normalized strength envelopes of a simplified two-phase

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 1 Observed oceanic spreading half-rates for the past 180 Myrs after a recent global compilation by Müller et al. (2008). Plate boundaries are in white, continents in dark gray. Abrupt changes in spreading rates reveal short-term variations in global plate motions, particularly visible in the South Atlantic (a) as well as in the Indian Ocean (b). Such rapid variations are unlikely to originate from global

changes in mantle driving forces, which occur on a longer time scale on the order of 50–100 Myrs as indicated by mantle circulation models. Instead, they are related to short-term variations in plate boundary forces caused, for example, by rapid growth of surface topography at convergent margins (see text). These observations point to the first-order importance of plate boundary forces in controlling global plate motions. (Courtesy of Elsevier © 2009)

lithosphere. Depth-dependent strength is parameterized via empirical laws established through laboratory experiments performed on quartzite, abundant in the upper 20 km of continental lithosphere, and olivine, which dominates at greater depths. The laboratory results indicate that strength increases linearly with overburden pressure in the upper, brittle part of the lithosphere; it then decreases exponentially with increasing temperature in the lower, ductile part (Kohlstedt et al. 1995). High strength in the upper lithosphere reflects the resistance of rocks to failure at low temperature, or to sliding past each other when already faulted. Experimental results indicate a simple linear relationship to parameterize this behavior (Byerlee 1978), with shear stress proportional to the normal pressure through a friction coefficient typically on the order of 0.6 (dashed envelope in Fig. 2). There is, however, mounting evidence for significantly lower values (in the range 0.01–0.15, see solid envelopes in Fig. 2) along faults and plate boundaries (Hickman 1991; Bird 1998; Suppe 2007).

Computer Models of the Faulted Lithosphere Coupled with Global Mantle Circulation Models

Lithospheric faults exhibit low friction, as we have noted. In other words, they are mechanically weak and experience low

stresses independently of the strain rate. It is therefore attractive to represent faults directly within the computational grid of numerical models of the lithosphere. This can be done, for instance, through the use of so-called contact elements, in an approach known as neo-tectonic modeling. Neo-tectonic models have reached considerable sophistication. They solve the equations of mass and momentum conservation, and compute the instantaneous force balance and associated plate velocities. They implement empirical, depth-dependent rheologies of the lithosphere, and account for ductile deformation in the lower crust as well as brittle deformation along faults. In some cases, they take advantage of the so-called thin-sheet approximation to reduce the computational complexity from 3-D to 2-D (Kong and Bird 1995) and to achieve greater computational efficiency.

Independent of advances in neo-tectonic models, there has been much progress in modeling the global circulation of the Earth's mantle (Tackley et al. 1994; Bunge et al. 1997; Zhong et al. 2000). Mantle circulation models (MCMs) account for the dynamic effects from a weak asthenosphere on the horizontal length-scales of the flow (Bunge et al. 1996), include internal heat generation from radioactivity, as well as a significant amount of heat from the core (Bunge 2005; Quere and Forte 2006; van der Hilst et al. 2007). Combined with constraints on the history of subduction, these models place first-

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 2 Normalized strength/depth profiles for a simplified two-layer continental lithosphere, plotted for three different fault friction coefficients and a strain rate in the range of 10^{-15} to 10^{-13} s $^{-1}$, typical of plate tectonics. Laboratory experiments performed mainly on quartzite and olivine (see text) indicate that lithosphere strength increases linearly with overburden pressure in the upper brittle part and decreases exponentially with increasing temperature in the lower ductile part. Note that the brittle part contributes a significant portion (70–80%)

of the total lithospheric strength, independently of the particular choice of friction coefficient and strain rate values. Experimental results suggest a friction coefficient around 0.6 (*dashed envelope*) for rocks under lithostatic pressure conditions, known as Byerlee's law. However, various independent evidences for weak faults suggest much lower values between 0.01 and 0.15 (*solid envelopes*), so that plate boundaries experience considerably lower stresses even for high strain rates. (Courtesy of Elsevier © 2009)

order estimates on the internal mantle buoyancies driving plate motions. Figure 3 shows the temperature distribution in the mantle from one recent model with more than 100 million grid points (Oeser et al. 2006), equivalent to a grid point spacing of 20 km and less throughout the model mantle. MCMs provide first-order estimates of mantle buoyancy forces but do not account for the complex processes in the lithosphere such the brittle failure. Similarly, neo-tectonic models include stresses originating within the lithosphere and realistic plate boundary forces. But they rely on assumptions of the mantle buoyancy field to complete the force balance. The logical step is merging the two model classes to simulate the coupled global mantle convection/plate tectonics system. This makes it possible to account simultaneously for plate boundary forces and mantle-related components of lithospheric force balance, and to predict variations in global plate velocities that one may test explicitly against the geologic record. Several authors have recently

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 3 Temperature distribution in the Earth's mantle from a recent, high-resolution 3-D global circulation model. Blue represents cold, denser material whereas red is hot and buoyant mantle. View is on Africa, coastline is in white, with continental topography in transparent green color scale. Present-day plate boundaries are outlined in blue. More than 100 million grid points discretize the Earth's mantle, equivalent to an average grid spacing of 20 km or less. Circulation models include radial variations in mantle viscosity (factor 40 increase from the upper to the lower mantle), internal heat generation from radioactivity, bottom heating from the core, and a history of subduction spanning the past 120 Myrs. A cold downwelling is visible beneath Tibet where the ancient Tethys Ocean subducted under Eurasia; a hot and buoyant upwelling is visible as well beneath the spreading triple-junction of the Antarctica, Africa, and Australia plates. The circulation model provides a realistic, first-order estimate of internal buoyancy forces driving global plate motions. (Courtesy of Elsevier © 2009)

undertaken such approach (Iaffaldano et al. 2006; Ghosh et al. 2008). Results are encouraging, and in the following, we review recent predictions of climate-related topography variations and their influence on plate velocities in the Southern Pacific, Southern Atlantic, as well as in the Indian Ocean that compare well with observations.

Recent Plate Motion Changes

Kinematics of the Southern Pacific and Atlantic, and Its Relations to Climate Variations and Topographic Growth in the Andes

Paleomagnetic (Gordon and Jurdy 1986; DeMets et al. 1994) and geodetic (Norabuena et al. 1999) data indicate a significant reduction (as high as 30%) of the Nazca/South America plate convergence over the past 10 Myrs. The timing of the slowdown is significant in that it is coeval with major growth of the Andes (Allmendinger et al. 1997) inferred from a variety of independent data (Gregory-Wodzicki 2000). Iaffaldano et al. (2006) tested the effect of topography on plate convergence by computing plate velocities before and after Andean topography growth, assuming mantle shear tractions from a MCM, as well as a low fault friction coefficient of 0.03 for the tectonic model. They performed two separate simulations of global plate motions, in order to estimate the increase of horizontal deviatoric force in the frictional region of the Nazca/South America interface arising from the gravitational collapse of the Andean belt, and its effect on the convergence rate. One simulation was based on present-day topography from the ETOPO 5 data set, as high as 5 km in the central Andes, to compute global plate velocities. A second simulation accounted for a lower topographic relief of continental South America, based on a reconstruction of Andean paleoelevation 10 Myrs ago (Gregory-Wodzicki 2000). Comparison of the two computed velocity fields predicts a 30% convergence reduction between the Nazca and South America plates (Fig. 4), and agrees well with the record of present and past plate motions. More importantly, the contribution of the momentum from the gravitational collapse of the large plateau has been estimated to be of some 10^{13} N/m along the central Andes. It should be pointed out that other mechanisms, such as temporal variations of friction along plate boundaries (Iaffaldano and Bunge 2008) and lateral buoyancy variations (Forte et al. 2009), may contribute to modify the convergence regime along the Nazca/South America margin to a minor extent. From Fig. 4, it is evident that the total convergence reduction is unevenly partitioned between the Nazca and South America plates. This can be understood by recalling that mantle shear tractions exerted on the lithosphere-base scale to first order with the basal surface area of the plate times its velocity. Because the Nazca plate is smaller than South America, a

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 4 Predicted plate motions in the hot spot reference frame from coupled global mantle convection/lithosphere dynamics simulations, corresponding to assumed Andean paleotopography 10 Myrs ago (red) and present-day topography (blue). Plate boundaries are in black and continents in gray. AF Africa, AN Antarctica, AR Arabia, AU Australia, CA Caribbean, CO Cocos, EU Eurasia, IN India, NA North America, NZ Nazca, PA Pacific, PH Philippine, and SA South America. IN and AU are treated as separate in the computational grid, based on recent evidences of plate separation (see text and Figs. 6 and 7). Note that a lower paleotopography assumed for the Andes 10 Myrs ago results in a

predicted NZ/SA convergence of 10.1 cm/year at long 71.5°W, lat 25°S, whereas present-day topography results in a predicted convergence of 6.9 cm/year at the same position (see text). The rates compare remarkably well with observations inferred from a variety of data, which indicate a 30% reduction of NZ/SA plate convergence from 10.3 cm/year to 6.7 cm/year over the past 10 Myrs. The modeling results suggest that the reduction of NZ/SA convergence is caused by resisting plate-margin forces associated with the topographic load of Andes (see text). Similar numerical models moreover confirm that frictional variations along the boundary, arising from variations in trench sediment infill, are insufficient to explain the record of plate motion. (Courtesy of Elsevier © 2009)

higher velocity reduction is required in the momentum balance for mantle shear tractions to equilibrate topography-generated plate-boundary forces along the margin. Iaffaldano and Bunge (2009) took a step forward and used global models to predict the history of relative motion for plates adjacent to Nazca and South America (Pacific, Africa, Antarctica), which are shown in Fig. 5. Agreement between models and observations is remarkable, implying that the resisting forces along the Nazca/South America plate boundary are responsible for driving plate motion changes also in the Southern Atlantic and Southern Pacific regions.

Plate Motion Changes in the Indian Ocean

While instantaneous calculations of the plate tectonic momentum balance cannot be taken to model the temporal evolution of plate boundaries, they do allow us to test the effects of variations in plate geometry on global plate motions, and in particular the creation of new plate boundaries. From the principle of inertia, it follows that any such event would invariably trigger plate motion changes due to repartitions in the budget of basal drag and plate boundary forces. A recent such episode is thought to have occurred in the Indian Ocean, where a variety of evidence has been interpreted as the generation of a diffuse boundary between the India and Australia plates, dated between 8 and 20 Myrs ago (Wiens et al. 1985; Gordon et al. 1998). Ocean-floor

deformation at about 8 Myrs is documented from buckling of marine sediments (Weissel et al. 1980). Ongoing deformation in the Indian Ocean is also supported by pronounced ($M_s > 6.5$) and localized seismicity (Stein and Okal 1978) along the northern portion of the Ninety East Ridge (see inset in Fig. 6), suggestive of left-lateral strike-slip motion. Figure 6 shows the observed convergence history of India and Australia relative to Eurasia since early Miocene based on geodetic (Sella et al. 2002) as well as paleomagnetic (Cande and Stock 2004; DeMets et al. 1994; Gordon and Jurdy 1986; Merkouriev and DeMets 2006) data collected along the Carlsberg and South East Indian ridges (labeled respectively as CBr and SEIr in the inset). Within error-bars, convergence rates are almost indistinguishable between 20 and 11 Myrs ago, suggesting that India and Australia behaved as one single plate with presumably little deformation occurring in between. Over the past 11 Myrs, however, their convergence to Eurasia differs distinctly. While India slowed down by almost 2 cm/year, convergence of Australia to Eurasia remained almost steady, with only some 0.5 cm/year of reduction. Timing of the India/Eurasia plate-motion change coincides reasonably well with the occurrence of diffuse deformation in the Indian Ocean. More relevant is the fact that Tibet had attained most of its current elevation (Tapponnier et al. 2001) prior to the slowdown of the Indian plate and prior also to the presumed formation of the India/

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 5 Predicted and observed relative plate motions in the South Atlantic and South Pacific over the past 10 Myrs for a set of adjacent plate pairs: PA/NZ, NZ/SA, NZ/AN, and SA/AF (abbreviations as in Fig. 6). *Black bold segments* in the small inset indicate positions along plate boundaries (*thin black*) at which relative motions have been computed. Observed plate motions (with *error bars*) inferred from paleomagnetic and geodetic data are represented by *black dots*, while *empty squares* indicate relative motions predicted from our simulations of the global coupled mantle/lithosphere system. The models explicitly account for the growth of the Andes over the past 10 Myrs, and demonstrate that the relative plate motion record can be entirely explained with the history of Andean orogeny. Our simulations thus point to the importance of far-field effects in plate tectonics and imply that resisting plate margin forces due to Andean growth account for about 18% of global plate motion changes over the past 10 Myrs (see Fig. 8). (Courtesy of Elsevier © 2009)

Australia plate boundary, implying that resistive plate boundary forces arising from the gravitational load of Tibet were already in place to act against convergence. Iaffaldano and Bunge (2009) tested explicitly whether plate-boundary forces from high Tibet are sufficient to explain the observed reduction of India/Eurasia plate convergence, once the former is separated from Australia by an additional plate boundary (Fig. 7). Specifically, they performed two distinct simulations of global plate motions, one with India and Australia cast as one single plate and the other with two plates built into the computational finite-element grid. A single India/Australia plate results in a predicted convergence of 5.2 cm/year at long 86°E, lat 27°N (Fig. 7a), whereas India being separated from Australia implies a convergence of 3.5 cm/year at the same position (Fig. 7b). The latter prediction compares remarkably well with the geodetic estimate (see Fig. 6). Finally, it is worth mentioning that simulations also predict an increased convergence between India and Australia,

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 6 Observed convergence of India (*red*) and Australia (*blue*) relative to fixed Eurasia over the past 20 Myrs. Convergence rates are computed through rigid-rotation Euler poles at long 86°E, lat 27°N of the India/Eurasia margin. Present-day values (*squares*) are derived from geodetic techniques while the paleomagnetic record (*solid lines*) is computed by averaging finite rotations of magnetic anomalies identified along the Carlsberg and South-East Indian ridges (labeled respectively, as CBr and SEIr in inset). Note that convergence rates are very similar between 20 and 11 Myrs ago, when India and Australia appear to behave as one single plate with presumably little internal deformation. The convergence relative to Eurasia differs more distinctly over the last 11 Myrs, when India and Australia slowed down by almost 2 cm/year and 0.5 cm/year, respectively. Inset shows locations of identified unconformities of sediments (*magenta dots*) as well as great (*Ms > 6.5*) earthquakes (*green dots*) indicating left-lateral strike-slip motion in the northern portion of the Ninety East Ridge (*orange contours*). Those evidences suggest diffuse deformation in the Indian Ocean particularly pronounced during late Miocene and have been interpreted as separation between the India and Australia. Plate boundaries are in *white* and continental topography in *gray color* scale. (Courtesy of Elsevier © 2009)

concentrated in the Indian Ocean, compatible with the aforementioned geologic and geodetic record.

Conclusions

Recent results indicate that joint modeling of the mantle/lithosphere system begins to achieve a level of maturity that allows explicit testing of a range of hypotheses on the force balance in plate tectonics and identifying key controlling parameters. While buoyancy forces from MCMs contribute significantly to the dynamics of plate motion, it is clear that plate boundary forces are of sufficient magnitude relative to these driving forces to affect plate motions and plate deformation, and to initiate rapid plate motion changes. One key controlling parameter in regulating plate velocity is the elevation of large mountain belts, because their topographic load

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 7 Predicted India (IN) plate motion relative to Eurasia (EU) from two distinct simulations with India and Australia (AU) acting, respectively, (a) as one single and (b) as two separate plates, where plate boundaries in our computational mesh are shown in *bold white* and finite elements in thin white. Plate motions are computed at long 86°E, lat 27° N. Abbreviations of plate names as in Fig. 6. Note that a single India/

Australia plate results in a predicted convergence of 5.2 cm/year relative to EU, incompatible with the geodetic estimate. Two separate plates result in a convergence of 3.5 cm/year of IN relative to EU, similar to the present-day observation. In the latter scenario, resisting forces from the gravitational load of Tibet act only against the smaller India plate and are thus more effective in slowing the convergent motion. (Courtesy of Elsevier © 2009)

consumes a considerable amount of the driving forces available in plate tectonics, as much as 10^{13} N/m. Along the Nazca/South America plate boundary, these forces are sufficient to reduce the convergence rate over the past 10 Myrs by some 30%. This reduction is, however, not an isolated episode of a rapid plate motion slow down. Instead, many such variations are documented from the global compilation of Müller et al. (2008), which points to the importance of topography and erosion in the global tectonic system (Cloetingh et al. 2007). The fact that models accurately predict the spreading history of the Pacific/Nazca, Nazca/South America, Nazca/Antarctica, and South America/Africa plate boundaries is of equal interest. The result is not entirely surprising and arises from the kinematic constraints of plate tectonics on the sphere. This suggests that far-field effects cannot be neglected in the geologic record at least in some cases. The strong influence of mountain belts on the plate tectonic force balance could have important implications. In an influential paper, Raymo and Ruddiman (1992) advanced the notion that Cenozoic climate change may have been caused by the uplift of Tibet. In other words, the rise of large mountain plateaus may act as a tectonic force on climate (Strecker et al. 2007). Low erosion rates have been implicated as a prerequisite for the creation of large mountain plateaus (Sobel et al. 2003; Cliff and Vannucchi 2004). This implication suggests conversely that climate can act – through large topography – as a force in plate tectonics. Overall, a significant portion of recent

changes in global plate motions can be attributed to topography-related forcing along plate boundaries rather than to mantle buoyancy. These findings are summarized in Fig. 8, where the relative plate motion changes observed globally over the past 10 Myrs are plotted. Green and red bars show variations in plate motion that are related, respectively, to the growth of the high Andes or to the presumed recent separation between India and Australia, and amount to about 35% of the total change over the Earth surface. This remarkable first-order result clearly demonstrates the ability of plate boundary forces to affect the global plate velocity field. The level of maturity achieved by neo-tectonic simulations coupled with 3-D MCMs thus allows geodynamicists to make explicit predictions of the plate tectonic force balance that can be tested against the geologic record of present and past plate motions.

Plate Motions in Time: Inferences on Driving and Resisting Forces, Fig. 8 Observed variations of adjacent-plates motions over the past 10 Myrs. Abbreviations of plate names as in Fig. 6. For each couple of adjacent plates, variations are computed as magnitude of difference between relative rotation poles at 10 Myrs, derived from paleomagnetic reconstruction, and at present day, obtained through geodetic techniques (GPS). The Cocos oceanic plate is not considered, since a geodetic estimate for its rotation pole is not available. Variations of AF/SA, AN/NZ, NZ/SA, and NZ/PA adjacent-plates systems (*green bars*) can be entirely explained through the effect of Andean growth

(see Figs. 6 and 7). They amount to about 18% of the global relative motions changes over the past 10 Myrs. Variations of IN/EU as well as IN/AU relative motions (*red bars*) can be entirely explained through the effect of separation between India and Australia (see Fig. 7). They amount to about 17% of the global relative motions changes over the past 10 Myrs. Thus, our models of mantle/lithosphere dynamics explicitly predict about 35% of the global plate motion changes observed over the past 10 Myrs from two well-identified tectonic variations. Plate Tectonics, Precambrian

Y. J. Bhaskar Rao, T. Vijaya Kumar and E. V. S. S. K. Babu
Geochronology Division, CSIR-National Geophysical
Research Institute, Hyderabad, India

Definition

Precambrian (>541 million years, Myr) is divisible into the Hadean Eon (>4.0 billion years, Gyr), Archean Eon (4.0–2.5 Gyr), and the Proterozoic Eon (2.5–0.54 Gyr). The Archean and Proterozoic Eons are further divisible into Eras: Eo-archean (4.0–3.6 Gyr), Paleo-archean (3.6–3.2 Gyr), Meso-archean (3.2–2.8 Gyr), Neo-archean (2.8–2.5 Gyr), Paleo-proterozoic (2.5–1.6 Gyr), Meso-proterozoic (1.6–1.0 Gyr), and Neo-proterozoic (1.0–0.541 Gyr). The Phanerozoic Eon corresponds to <541 Myr. These Era names are also used with no hyphen.

Zircon (ZrSiO_4) is a mesosilicate found as an accessory phase in a wide compositional range of igneous, metamorphic, and sedimentary rocks of all ages. Zircon crystallizes in silicate melts and incorporates a wide range of high field strength incompatible elements; most common is Hafnium (Hf) with abundance ranging generally up to 4% by weight. Zircon is used widely in geochronology by the U-Th-Pb method of radiometric dating.

Introduction

Compared to other terrestrial planets that have basaltic (mafic) crusts, Earth is unique in having a prominent felsic (continental) crust alongside a mafic (oceanic) crust and most interestingly, a long sustained “Plate Tectonics” geodynamic regime (Taylor and McLennan 1985; Stevenson 2003; Rudnick and Gao 2014). In general, Earth’s continental crust is significantly thicker than the oceanic crust and is the principal archive of a rock record that dates back to ~ 4.0 Gyr. Therefore, understanding the geodynamic processes that underpin the formation of continents is fundamental to decoding the complex evolutionary history of the Earth and the terrestrial planets. In general, the geodynamic styles reflect how the planets lose their internal heat and plate tectonics represents a rather unusual mode of cooling (Sleep 2005; Lenardic 2018). The basic tenet of the plate tectonics paradigm is the observation that Earth’s lithosphere, a torsionally rigid thermal boundary conductive layer overlying the convective asthenosphere, comprises more than a dozen fragments, the “Plates”. Plate tectonics describes the essentially horizontal relative motions between the plates on the nearly-spherical surface of the Earth, in terms of the rotational pole and angular velocity. The loci of orogenic (mountain building) processes are plate boundaries that are mainly of three types: (1) divergent, (2) convergent, and (3) transform. The oceanic crust and the underlying depleted lithospheric mantle is created at divergent boundaries such as the Mid Ocean Ridge (MOR) system. This lithosphere is transported away from the MOR by the transform fault system. Formation of continental crust is a consequence of orogenic processes associated with long lived magmatic arcs along convergent plate boundaries, where the oceanic lithosphere subducts beneath oceanic or continental lithospheric plates. Along these subduction zones, calc-alkaline magmatism, due to hydrous melting of the mantle wedge overlying the subducting lithosphere, is a key product of the “subduction factory” (Keleman et al. 2004; Tatsumi 2005). Accretion of magmatic arcs and a variety of other terranes results in the development of continents and supercontinents (Cawood and Buchan 2007; Cawood et al. 2009; Santosh 2010; Nance et al. 2014). Because steep subduction of the oceanic lithosphere is the principal driver of plate tectonics on modern (Phanerozoic) Earth, the process is commonly referred to as “subduction tectonics,” the hallmark of modern style plate

tectonics (Forsyth and Uyeda 1975; Stern 2005; Hamilton 2007). Two contrasting end-member types of orogenic systems operate on modern Earth: (1) the dominantly accretionary or the external type characterized by a significant juvenile crustal component, e.g., the Circum Pacific orogen (arc) system, and (2) the dominantly collisional or interior orogens that are characterized by composite terranes of juvenile and recycled crustal components, e.g., the Indonesian-Himalayan-Alpine mountain belt where terrane accretion involving “Wilson-cycle” (Wilson 1968) processes results in the formation of large continental masses (Stern 2005; Cawood and Buchan 2007; Santosh 2010; Collins et al. 2011; Nance et al. 2014).

Unlike in the Phanerozoic Eon, where the paradigm of plate tectonics and Wilson-cycle processes constitutes a robust and unifying mechanism in which to explain not only the orogenic processes of crust formation, recycling, preservation but also the complex interactions between the solid earth, biosphere, and atmosphere relevant to evolution of life and climates, there is yet no consensus on a global geodynamic framework for the early Earth, especially during the Hadean and Archean Eons (Harrison 2009; Kemp et al. 2010, 2015; Collins et al. 2011; Bédard 2013, 2018; Cawood et al. 2013; O’Neill and Debaille 2014; Roberts and Spencer 2015; Mueller and Nutman 2017; Harrison et al. 2017; Hawkesworth et al. 2017; O’Neill et al. 2018). Many fundamental and long standing questions, such as *why did the Earth adopt plate tectonics?* and *since when was plate tectonics operative on Earth?* remain challenging and unresolved problems in the evolution of the planet (de Wit and Ashwal 1995; Condie and Pease 2008; Ernst 2009; Cawood et al. 2018). While some authors propose that plate tectonics, *in some form*, operated during the Hadean Eon (Harrison 2009; Tarduno et al. 2015; Furnes et al. 2014; Kusky et al. 2018), and some others favored an Archean onset (Sleep 2005; Parman et al. 2001; Smithies et al. 2003, 2005; Cawood et al. 2006, 2013; Condie and Kroner 2008; Dilek and Polat 2008; Naeraa et al. 2012; Korenaga 2013), others favor a much later beginning in the Earth’s history, viz., during the Neoproterozoic (Davies 1992; Hamilton 1998, 2007; Stern 2005, 2007; Dewey 2007; Brown 2008). Currently the debate focuses on the onset of modern style plate tectonics, clearly implying steep geotherms rather than *any* horizontal plate motion.

One other important mechanism by which planetary bodies lose internal heat to the surface is volcanism. For instance, Jupiter’s moon, Io is characterized by a much higher surface heat flow than modern Earth. Io cools through intrusive magmatism and volcanism with “heat pipes” as the plumbing conduits (Moore and Webb 2013) rather than plate tectonics. Away from the plate boundaries on modern Earth, “mantle plumes” and “hot spots” contribute to intense volcanism leading to the development of oceanic plateaux and large igneous provinces. Mantle plumes that are posited to originate from deep thermo-chemical boundary layers,

such as either the core-mantle boundary or the D'' layer (~660 km), account for a minor part of the planet's heat loss (Morgan 1971; Lay et al. 2008). Although not mutually exclusive, the relative importance of plate and plume tectonics (broadly, horizontal and vertical tectonic styles) in terms of the growth of continental crust through geologic time has long been a matter of debate (de Wit and Ashwal 1995; Bédard 2006; Van Kranendonk 2010; Gerya 2014; Griffin et al. 2014; Harris and Bédard 2014; Korenaga 2018). There is no dispute that Earth has been on a cooling trajectory since its very early history and that even during the Archean, the mantle was hotter by ~250 °C and the radiogenic heat production was three to five times higher than the present (Abbott et al. 1994; Korenaga 2006; Labrosse and Jaupart 2007; Herzberg et al. 2010). This has a direct bearing on the thickness, composition, and rheology of early crust and forms the basis for rationalizing the observed secular changes in the global geologic record and the geodynamic regime, especially in the context of the onset of plate tectonics. Demonstration that plate tectonics operated at any given time requires evidence for lithospheric subduction and independent plate motions. However, since the oldest oceans on present Earth are not older than Jurassic (201–145 Myr), one is forced to consider the geological record on continents preserved in the Precambrian shields, which include Archean cratons that archive Earth's most ancient geologic record.

Over the last three decades, research on early Earth processes has gained immensely from: (1) petrological and geochemical constraints on the genesis of predominant lithologies of Archean cratons; (2) in-situ zircon U-Pb geochronology and Hf±O isotopic compositions, especially on Hadean and Archean detrital zircon grains from sources such as the Jack Hills metaconglomerate/quartzite, Yilgarn craton, Western Australia (Wilde et al. 2001; Harrison 2009; Belousova et al. 2010; Kemp et al. 2010, 2015; Voice et al. 2011; Condie et al. 2011; Griffin et al. 2014; Roberts and Spencer 2015; Harrison et al. 2017; Hawkesworth et al. 2017; Mueller and Nutman 2017); (3) numerical modeling of geodynamic processes (Korenaga 2013; O'Neill and Debaille 2014; Gerya 2014; Sizova et al. 2014, 2015); and (4) remote observation of terrestrial planets and study of extra-terrestrial materials (e.g., Moore and Webb 2013; Harris and Bédard 2014; O'Neill et al. 2017; Lenardic 2018). Drawing from this global endeavor, we summarize here the different perspectives on early Earth geodynamics and the debate on the onset of modern-style plate tectonics on the planet.

Modern-Style Plate Tectonics and Criteria for Recognizing Plate Tectonics in the Precambrian Record

In its initial conceptualization, plate tectonics offered a purely kinematic description of how lithospheric plates move and

interact with one another on the nearly spherical surface of the Earth. There was little clarity on the forces that cause plate motions. Notwithstanding the traditional view that the asthenospheric convection powers contemporary plate motions, modern geodynamicists find an increasing consensus for predominance of “top-down tectonics” (Anderson 2001), at least during some stages in the Earth's history, and suggest that plates drive themselves as they organize the overall mantle convection (Davies 1999; Hynes 2005). The lithosphere is buoyant when new oceanic crust is created at the MOR. As the lithosphere ages and moves away from the MOR, it cools (conductively), thickens, and increases in density leading to a buoyancy-crossover in the lithosphere–asthenosphere system. On the present Earth, such a crossover occurs in 20–40 million year intervals. This “ridge-push” coupled with “gravitational descent” of the lithosphere in the subduction zones contributes to much of the plate motion. Based on seismic tomography, it is evident that the lithospheric slabs on Earth reach great depths, typically 1100–1300 km, and possibly down to the core-mantle boundary (Van der Hilst et al. 1997). While the “slab pull” of the sinking lithosphere and the associated “slab suction” of the entrained ambient mantle at subduction zones move the plates (Conrad and Lithgow-Bertelloni 2004), while the viscous resistance of the asthenosphere impedes plate motion. Resistance to the sinking lithosphere is also from dissipation forces that are manifest as deformation (mainly faulting and bending) in the subducting slab and phenomena such as regional mantle down swelling. The nature and extent of equilibrium between the driving and resisting forces is indicated by the limited range of the observed plate velocities, which possibly did not exceed ~17 cm/year, for instance, during the Mesozoic drift of the Indian lithospheric plate, a case of extremely rapid plate motion.

Recognizing the on-set of modern-style plate tectonics on planet Earth involves tracking the manifestation of the processes in the geological record. For instance, evidences for the creation of new oceanic lithosphere, the existence of “ocean-plate stratigraphy”, subduction processes where the lithosphere is returned to the mantle, transform and transcurrent faulting and so on at any given time. The problem of preservation of the diagnostic criteria figures prominently, as the evidence in all likelihood, can be fragmentary and incomplete owing to obliteration by tectonic and surface processes. From the theoretical considerations presented in the foregoing sections, the modern-style plate tectonics is not only unusual in a planetary perspective, but also in the Earth's evolutionary history. Thus, the Huttonian uniformitarian approach “The present is the key to the past” may not be entirely helpful to understand the Earth's earliest tectonic history (Stern 2008). In any case, best approaches should consider multiple working hypotheses and methodological uniformitarianism emphasizing upon constancy of natural laws rather than substantive uniformitarianism invoking uniform geological processes through time (Stern 2008).

Lithotectonic elements of plate convergence could be quite diverse and combined interpretation of data from different disciplines assumes importance. Thus, a combination of information including geological structures, lithology, geochronology and isotope geochemistry, magma-type, metamorphic conditions, P-T-t paths, paleomagnetic evidence for relative motion between terranes and 2-D/3-D geometry based on geophysical data provide insights into geodynamic processes in space and time. Some of the most robust criteria for recognizing the operation of the plate tectonics in the past that were at the core of the debate are as follows. In general, different authors apply the criteria in different ways. For example, while some consider when a particular assemblage or property first appeared, others emphasize on when it became common. Thus, the inferences on the onset of plate tectonics on the Earth could be quite subjective, even by the same criterion.

Ophiolites: Ophiolites are slices of the oceanic lithosphere tectonically emplaced onto the continental margins or incorporated into accretionary prisms and could be reliable indicators of past plate tectonics. As indicated in the early work (e.g., Coleman et al. 1965; Penrose Conference 1972), a complete ophiolite sequence ocean-plate stratigraphy would include a succession (from top downward) of pelagic sediments, pillow basalt, sheeted dykes, isotropic gabbros, ultramafic cumulates, and tectonized ultramafites (lherzolite and harzburgite), the latter representing components of the depleted mantle. However, generally, fragmentary and dismembered sequences are encountered in Precambrian terrains. Well preserved ophiolites are known from many Neoproterozoic (up to ca. 1.0 Gyr old) and younger terrains (Stern 2008; Ernst 2007, 2009). Some of the better-preserved Neoproterozoic ophiolites include Purtuneni ophiolites, Canada (Scott et al. 1992), and Jormua ophiolites, Finland (Peltonen et al. 1996), although ophiolites as old as ca. 3.8 Gyr (the Isua suite, Greenland; Furnes et al. 2007) have been proposed, they remain controversial (also see Bickle et al. 1994). Different types of ophiolites have been proposed and described over the last two decades based on a better characterization of the petrology, structure, and composition of the oceanic crustal sections. These include the magma-poor and magma-rich types and discrete ophiolite types that represent the near-MOR segments as against those at supra-subduction settings (Furnes et al. 2014; Kusky et al. 2018 and references therein). Current views on ocean plate stratigraphy also appreciate the spatio-temporal variations in the sedimentary and magmatic deposits on to the ocean floor that are distinct from the MOR and the subduction zone environments. This is important because eventually they all get transported, scrapped-off into the accretionary wedge, where the packages get imbricated and strongly deformed. Thus, an ophiolite may include pillow lava grading upward into pelagic chert, limestone, banded iron formation, shales, and turbidites from both proximal and distal sources and not comply strictly with the

Penrose definition of ophiolites. These suites may form structurally complex tectonic melanges marked by thrusts and nappe complexes. Such packages currently described from ancient terranes of all ages support the view that plate tectonics may have operated since the late Hadean Eon. Some examples across the timescale include the Archean Nulliak greenstone belt, Labrador, the 3.8 Gyr Isua greenstone belt, W. Greenland, and the ~3.3 Gyr Barbarton greenstone belt, South Africa, which are considered to be examples of Paleoconvergent plate boundaries or interpreted as relics of ancient accretionary orogens (Komiya et al. 2015; de Wit et al. 2018; Kusky et al. 2018). Some authors, e.g., Condie (2015), favored a definition restricting usage of the term “ophiolite” in Archean terranes to fragments of oceanic crust $\pm$ mantle, i.e., formed at an oceanic ridge, but not at the arc. By such a filter, ophiolites begin to appear in Paleoproterozoic, around 2.0 Gyr although some dismembered older (ca 2.5 Gyr) examples may also qualify.

Blueschists, low-T eclogites, and paired metamorphic belts: In modern subduction systems, the down going oceanic lithospheric slab depresses isotherms creating a low- dT/dP environment. Fluids and melts from the slab generate high- dT/dP environments in the overlying mantle wedge. This leads to the formation of “paired metamorphic belts” with the characteristic metamorphic assemblages (Oxburgh and Turcotte 1971; Miyashiro 1972; Brown 2010). Typically, they form on the overriding plate with the high-P low-T (blueschist facies) terrane next to the trench, whereas the low-P high-T terrane (greenschist facies) develops near to the arc. Paired metamorphic belts represent the thermal structure of a mature subduction zone (Van Keken et al. 2002; Kelemen et al. 2004). As these belts are usually very wide, tens of hundreds of kilometers, they could be robust features that survive several episodes of orogeny and erosion (Stern 2008). In a paired metamorphic belt, accretionary convergent margins are preserved as broad zones, whereas the erosional boundaries could be much narrower (Stern 2008 and references cited therein).

Blueschists are metamorphosed mafic rocks bearing predominantly a sodic amphibole that stabilizes at high-P, low-T typical of Pacific-type of orogenic belts. Best studied examples are the Franciscan and Sanbagwa terrains (Ernst 2003). The oldest known blueschists are Neoproterozoic (800–700 Myr; Maruyama et al. 1996) and undisputed pre-Neoproterozoic blueschists are virtually unknown. For many authors, the absence of blueschists in Archean terrains implies non-operation of plate tectonics (e.g., Stern 2005; Bédard 2006; Hamilton 2011), while for others, it implies subduction in hotter mantle temperature gradients and/or that the high-Mg content of Archean magmas inhabits the development of blueschist assemblages (e.g., Palin and White 2016).

Eclogites (s.s) are metabasalts and metagabbros that equilibrated at $P > 1.2$ GPa (>45 km) and $T (>600\text{--}650^\circ\text{C})$ with a characteristic pyropic-garnet and omphacitic-clinopyroxene-

bearing assemblage. Different types of eclogites have been described, but Coleman's group C (associated with glaucophane schists) and the "low-T eclogites" (Carswell 1990) could be reliable indicators of subduction process. Archean eclogites are rare and become abundant post Archean, mostly as mantle or crustal xenoliths in kimberlites and rarely in outcrop (Rollinson 1997). Study of eclogite inclusions in diamonds that originate in thick Archean SCLM suggests that the modern style subduction may not have occurred prior to ca 3.0 Gyr (Shirey and Richardson 2011).

UHP (Ultra High Pressure) terrains form when continental crust initially subducted to greater than 100 km returns to the surface through subsequent tectonic processes. Typical assemblages include coesite and diamond, indicative of 700–900 °C and 3–4 GPa, or more (Liou et al. 2004). Some of the oldest known UHP terranes are in Mali, ca. 620 Myr (Jahn et al. 2001) and Kazakhstan, 530 Myr (Maruyama and Liou 1998).

Batholiths: Mere presence of magmatic "island arc" features suggests modern-style plate tectonics with deep subduction (100–250 km). In such a setting from older terrains, volcanic rocks are usually removed by erosion, leaving behind well-preserved mid-crustal batholiths (Hamilton and Myers 1967; Stern 2002; Hamilton 2011). Felsic plutonic lithologies, well represented by Tonalite-Trondhjemite-Granodiorite (TTG) suites, dominate Precambrian plutons coalesced into batholiths.

Composition of igneous rocks: The relationship between tectonic setting and composition of igneous rocks has been a subject of considerable interest (see Pearce and Peate 1995; Pearce 2008). However, the diversity of sources, magmatic processes, and the problem of element mobility in secondary environments pose a serious challenge to "geochemical fingerprinting" of tectonic settings (Condie 2015). In general, the distribution of immobile trace elements and ratios (e.g., incompatible elements including Rare Earths, Y, Th, and High Field Strength Elements, such as Zr, Ta, Hf, and Nb) with similarity to modern arc magmas and the identification of certain magmatic associations like boninites and adakites in Archean granite-greenstone terranes have been used widely as evidence for operation of plate tectonics in the Archean (Foley et al. 2003; Kerrich and Polat 2006; Shirey et al. 2008).

The petrogenesis and tectonic setting of the Archean sodic TTG complexes, the most voluminous lithology of the cratons, especially the early Archean (>3.2 Gyr); has been a subject of considerable discussion (Moyen and Martin 2012; Laurent et al. 2014; Hoffmann et al. 2014). Recent models based on geological and geochemical observations and thermomechanical-numerical modeling at conditions similar to Eo-Mesoarchean times invoke melting of hydrated basalt at garnet amphibolite, granulite, or eclogite facies conditions in different tectonic scenarios including subduction, as well as the range of nonplate tectonic (no subduction) scenarios

and/or a combination of both (Rapp et al. 1991; Hill et al. 1992; Martin 1993; Abbott et al. 1994; Van Thienen et al. 2004; Smithies et al. 2005; Bédard 2006; Van Kranendonk et al. 2007; Van Kranendonk 2010; Moyen and Martin 2012; Sizova et al. 2015).

Seismic reflections of deep crust: In general, deep-crustal seismic reflection studies in many cratons indicated: (1) gentle to moderately dipping crustal detachments identified based on the geometry of reflections and truncations; and (2) reflections projecting from the lower crust into the upper mantle suggesting that the crust may have been thrust into the mantle (e.g., Yilgarn Craton, Australia, Drummond et al. 2000; Goleby et al. 2004; Kaapvaal craton, South Africa, de Wit and Tinker 2004; Dharwar craton, India, Vijaya Rao et al. 2015; Mandal et al. 2018). Neoproterozoic (2.7 Gyr) plate tectonics was inferred in the Superior craton, Canada, by the discovery of "mantle reflections" and interpretation that these reflections reflect "subduction scars" or "fossil subduction" (Calvert et al. 1995; Calvert and Ludden 1999; van der Velden and Cook 2005).

Palaeomagnetic data: The palaeomagnetic method offers a quantitative means to test relative motions between plates and the operation of Plate Tectonics during the Precambrian. In general, there is evidence in the Palaeomagnetic record that a modern-like geocentric axial dipole geomagnetic field with a weaker or comparable intensity to the present existed during the Phanerozoic and Proterozoic Eons. High quality palaeomagnetic data especially on magmatic associations like mafic dyke swarms could help in analyzing differential movements of continents at least since the Neoproterozoic (~3.0 Gyr) (McElhinny and Senanayake 1980; Pesonen et al. 2003; Evans and Pisarevsky 2008 and references cited therein). However, in the absence of precise geochronological data and poor constraints of field stability tests of remanence, the application of palaeomagnetic method to Archean terranes has been problematic.

Evolution of Earth's Geodynamic Regime and the Onset of Plate Tectonics

The Hadean Eon

Thermal models of planetary evolution suggest three principal modes of nonradiative planetary heat transfer (Sleep 2000): (1) magma mush oceans, (2) plume and plate tectonics, and (3) stagnant-lid convection (illustrated in Fig. 1 in corresponding stages). The magma mush ocean mode is, by far, the most energetic mode and probably characterizes the early Hadean tectonic style. The stagnant-lid convection, the least energetic mode, characterizes the present Venus and Mars and was possibly present on Earth episodically. In general, several simulations of Hadean geodynamic environments suggest the difficulty of sustained plate motion and

Plate Tectonics, Precambrian,
Fig. 1 Cartoon illustrating the evolution of global tectonic styles from the Hadean to Present involving three main stages. See text for more details. (Modified after Ernst 2007; Stern 2008 and references cited therein)

Stage I: Hadean (4.55–4.0 Ga)

Convecting magma/mush ocean

Stage II: Archaean-Proterozoic (4.0–1.0 Ga)

II.A. Proto-plate tectonics

Plume and deep mantle-driven circulation and formation of platelet (4.4–2.7 Ga) and supercratonic stage (2.7–1.0 Ga)

II. B. Unstable Stagnant Lithospheric Lid

Formation of oceanic and continental crust through mantle upwelling processes

Stage III: Modern-style plate tectonics <1.0 Ga

Passive mantle upwelling at mid-oceanic ridges and sinking of dense lithospheric plates at subduction zones.

subduction processes for the hotter mantle/lithosphere (Sizova et al. 2010; Rozel et al. 2017; O'Neill et al. 2017) during the early Hadean, plume induced subduction (Gerya et al. 2015), and impact triggered short-lived subduction events have been proposed (O'Neill et al. 2017). Nonplate tectonic scenarios such as stagnant-lid, heat pipes, and mantle plumes were also inferred in numerical simulations and thermo mechanical models (Touboul et al. 2012; Moore and Webb 2013; O'Neill and Debaille 2014; Gerya 2014). Following the condensation of the accreting hot Earth by

~4.57 Gyr, the planet may have witnessed further rapid increase in its internal heat ascribed to core-formation, radioactive decay of long-lived elements (U, Th, ^{40}K) and short-lived isotopes (e.g., ^{26}Al), bolide impacts, and very early impact of a Mars-sized body and such other factors (Wetherill 1976; Cameron and Benz 1991; Kleine et al. 2004; Elkins-Tanton 2008). As illustrated in Fig. 1 (stage I), this phase was succeeded by the formation of a near-surface magma mush ocean, several 100 km thick (Abe 1997; Davies 1999; Boyet and Carlson 2005), prior to 4.4 Gyr.

Early studies on the Jack Hills Hadean detrital zircon grains suggested their origin in felsic crust at ~4.4 Gyr and interaction with liquid water (Wilde et al. 2001; Valley et al. 2002). Thermodynamic considerations of mineral inclusions within Hadean zircons indicated conditions similar to modern subduction zones for the felsic hosts of the early Hadean zircons (Hopkins et al. 2008). Paleomagnetic considerations based on paleo-intensity of Hadean Jack hills zircon grains support plate tectonics prior to 4.1 Gyr (Tarduno et al. 2015). On the contrary, re-evaluation of the Jack Hills zircon U-Pb age-Hf and O isotopic data suggested the possibility of existence of a long lived mafic protolith for the felsic melts in which the zircons formed (Kemp et al. 2010, 2015). These isotopic systematics of the >3.8 Gyr zircons indicate that the early enriched mafic proto-crust may have resided deep beneath the surface, much similar to the highly enriched silicate reservoir, the UrKREEP on the Moon, which eventually contributed to the generation of KREEP-rich lunar igneous rocks with ages between 4.4 and 3.9 Gyr (reviewed by Iizuka et al. 2017). Such an interpretation supports the stagnant-lid tectonics (Debaille et al. 2013), a single lid with no relative motion for the early Earth. Debaille et al. (2013) infer a dominantly stagnant-lid regime for about ~700 million years (between 4.5 and 3.8 Gyr). Thus, combined interpretation of zircon isotopic data and numerical models suggests the relevance of dominantly stagnant-lid with episodic transient subduction-like events for the Hadean crust.

The Archean-Proterozoic Eons

Significant cooling of the Earth's crust (below the boiling point of water) by ~4.0 Gyr is inferred from preservation of the ~3.9 Gyr Isua volcano-sedimentary assemblages, western Greenland, which suggest the possibility that water-oceans marked the planet's outer rind by the Late Hadean times (Fig. 1, stage II a, b). No record of the Hadean crust older than the 4.03 Gyr component of the Acasta gneiss (Slave craton, Canada) (e.g., Bowring and Williams 1999; Mojzsis et al. 2014) is preserved and Eoarchean crustal remnants are scarce. Archean cratons consist predominantly of crust generated in the Neoproterozoic, while Paleoproterozoic to Mesoproterozoic crust is documented from few cratons (e.g., Nutman et al. 2002; Bleeker 2003; Van Kranendonk et al. 2007; Wu et al. 2008; Zeh et al. 2011; Arndt 2013; Turner et al. 2014; Wan et al. 2015; Komiya et al. 2015; Santosh et al. 2016; Mueller and Nutman 2017; Jayananda et al. 2018; Sreenivas et al. 2019; Bhaskar Rao et al. 2020). Since the 1960s, Archean geologists recognize that the large-scale granite-greenstone structures in the Archean cratons are divisible into two broad types: the dome and keel type and the orogenic linear belt type and the geodynamic models comprise two broad scenarios: "vertical" and "horizontal" tectonic regimes (Windley 1984; de Wit and Ashwal 1995 for a review). The former has been generally ascribed to mantle upwelling

(mantle plumes) and in some regions models invoking gravity driven Rayleigh-Taylor type instabilities and density inversions leading to sinking of dense volcanic-rich greenstone sequences and rising of felsic diapirs from the underlying crust producing dome and keel structures were proposed, typified by examples in Rhodesian and Pilbara cratons (Bédard 2006; Van Kranendonk et al. 2007; Wiemer et al. 2018). Horizontal tectonics in the Archean context is broadly analogous to Phanerozoic Wilson-type plate tectonics, but invokes subtle differences mainly due to higher mantle potential temperature and crustal heat flow during the Archean (Windley 1984; de Wit and Ashwal 1995; Kerrich and Polat 2006; Dewey 2007; Condie and Pease 2008; Ernst 2009). However, these "end-member" models are neither adequate nor mutually exclusive and a variety of complex mixed-mode scenarios involving, for example, multiple subduction zones and intermittent mantle plumes have been proposed (e.g., Wyman et al. 2002; Bédard 2006 and references therein).

It is now widely appreciated that as much as 73% of the present volume of Earth's continental crust may have been extracted from the mantle by the end of the Archean (Belousova et al. 2010; Dhuime et al. 2012; Cawood et al. 2013) and major peaks in the accretion of Archean juvenile crust centered around 3.0, 2.7 and 1.9 Gyr (Condie et al. 2011; Voice et al. 2011). Many researchers favor a view that the late Paleoproterozoic/early Mesoproterozoic (ca. 3.2–3.0 Gyr) marked a transition in the planet's geodynamic regime from a dominantly vertical (driven by mantle upwelling) towards dominantly horizontal (some form of plate tectonics) geodynamic regime (summarized by Hawkesworth et al. 2017; Condie 2018). This view is increasingly in favor in the light of the convergence of many different datasets including field geological observations, paleomagnetic, geochemical, ore deposit studies, and global-scale zircon U-Pb age-Hf±O datasets (Dhuime et al. 2012, 2018; Cawood et al. 2013; Tang et al. 2016; Hawkesworth et al. 2017 and references therein). The numerous geological and lithotectonic changes documented during this interval are linked directly or indirectly to the cooling of Earth's mantle and corresponding changes in convective style and the strength of the lithosphere. These data suggest a distinct change in the character, composition, and thickness of the continental lithosphere around ~3.2–3.0 Gyr. Some of the important changes include: (1) increasing proportion of basalts with "arc-like" mantle sources and the preponderance of K-rich granites; (2) the development of a stable continental lithosphere (Carlson et al. 2005; Condie and Kroner 2008; Moyen and Martin 2012); (3) the onset of a Great Thermal Divergence in the mantle (Condie et al. 2016); (4) appearance of eclogite inclusions in diamonds (Shirey and Richardson 2011); (5) an increase in the volume of crust generation marked by a change in the slope of the continental growth curve at ~3.0 Gyr estimated from the zircon age-Hf data (Belousova et al.

Plate Tectonics, Precambrian, Table 1 Earth’s geodynamic transition towards plate tectonics. (Summarized from Hawkesworth et al. 2017)

Stage-1 (the early ~15 Myr)	Initial accretion of Earth, giant impactors, core formation, radioactive decay of long and short-lived nuclides, formation and partial crystallization of deep mantle silicate magma ocean, development of an undifferentiated mafic protocrust
Stage-2 (4.5–3.0 Gyr)	Generation of crust in a pre-plate tectonic regime with episodic short lived plate tectonics alternating with nonplate tectonic mechanisms. Little or no lithospheric record for the first 600 Myr until the termination of the late heavy bombardment event around 3.9 Gyr. Potential mantle temperatures ~250 °C hotter than present day upper mantle and asthenospheric temperatures ~1350 °C at around 3.9 Gyr, which imply reduction in lithospheric rigidity inhibiting deep level lithospheric subduction. Generation of lithosphere in zones of mantle upwelling and melting, accompanied by lithospheric delamination. Start of oxygenation of atmosphere by ~3.5 Gyr
Stage-3 (3.0–1.7 Gyr)	Cooling of mantle to an extent enabling subduction of semi rigid plates. Increased generation of differentiated juvenile crust through hot subduction at relatively high geothermal gradients. Stabilization of pre 3.2 Gyr cratons with a change in crustal growth rates around 3.0 Gyr
Stage-4 (1.7–0.75 Gyr)	Significant increase in the atmospheric oxygen levels during the early Proterozoic, “the Great Oxidation Event,” along with significant increase in the volume and thickness of continental lithosphere, change to more felsic continental crust and its widespread exposure. An increase in geologic record of continental collisions, assembly and break-up of Supercontinents; Nuna and Rodinia
Stage-5 (<0.75 Gyr)	Initiation of modern cold subduction at relatively low geothermal gradients, common appearance of high- to ultrahigh-pressure metamorphic rocks. The episodic development and break-up events related to Supercontinents Gondwana and Pangea. Increased in the destruction (recycling) of continental crust. Increase in the oxygen levels of atmosphere and deep oceans, widespread development of phosphate and evaporates promoting metazoan evolution

2010; Dhuime et al. 2012, 2018); (6) a progressive increase in the appearance of collisional orogens following 3.0 Gyr, as well as ophiolites and global large igneous provinces in the geologic record (Condie 2018). On the other hand, as stated earlier many authors continue to opine that truly modern-style subduction was initiated around the Neoproterozoic (~1.0 Gyr, Fig. 1, stage III) (also see Stern 2018). Hawkesworth et al. (2017) summarized the temporal changes in the tectonic processes controlling the evolution of Earth’s lithosphere in a model comprising 5 stages (Table 1). The boundary between each stage corresponds to a change in the character of the lithosphere and dominant tectonic process.

Summary

Plate tectonics is a characteristic geodynamic feature of the Phanerozoic Earth. However, its onset on the planet remains controversial with estimates ranging from the Hadean to the Neoproterozoic. There is an increasing consensus for the view that the change from a nonplate tectonic Earth to one in which plate tectonics dominated was not abrupt and may have extended over hundreds of millions of years about 3.0 Gyr. Several changes in the behavior and character of the lithosphere around 3.0 Gyr are interpreted in terms of a geodynamic transition from a nonplate tectonic mode to the birth of plates and followed by sustained plate tectonics through the Proterozoic Era. The dynamics of such a transition are believed to be distinctly nonlinear. The predominant tectonic regime in the Hadean was stagnant-lid convection, with intermittent recycling events implying multiple episodic subduction initiation events with progressively increasing preservation potential of the manifestation of plate tectonic processes.

Plate-driving forces. The forces exerted on Earth's tectonic plates that produce their observable horizontal motions.

Introduction

Since the advent of the theory of plate tectonics in the 1960s, it has been postulated that the forces that drive the observed horizontal motions of Earth's tectonic plates are produced by the process of thermal convection in the mantle. The proposition that such motions could be produced and sustained over very long geological time scales in a rocky shell, comprising the lithosphere and underlying deep mantle, that behaves as an imperfect elastic solid through which seismic waves travel, was initially viewed as a serious obstacle to the acceptance of the mantle convection hypothesis of plate motions (e.g., Jeffreys 1972). This obstacle was eliminated with the recognition, amply confirmed by high-temperature deformation experiments on minerals (e.g., Evans and Kohlstedt 1995), that the rheology of the mantle allows steady-state creeping flow when subjected to long-term shearing stresses, provided the ambient temperature is sufficiently high (Poirier 1985).

The relationship between the mantle shear stress and deformation (measured in terms of strain rate) is characterized by an effective viscosity. Experimental and theoretical studies of the rheology of mantle minerals indicate that their effective viscosity is strongly dependent on pressure, temperature, and chemical composition (e.g., hydration). For sufficiently low ambient stress, mantle viscosity also depends on grain size, yielding linear (Newtonian) diffusion creep, whereas for high ambient stress, the viscosity depends on stress magnitude and is independent of grain size, yielding a nonlinear (power-law) dislocation creep (Karato and Wu 1993). The temperature dependence of mantle viscosity gives rise to a lithospheric layer that is stiffer and less deformable than the much hotter, less viscous upper mantle. Indeed, the very existence of tectonic plates, behaving as effectively rigid bodies, with little surface deformation is generally explained in terms of the strong temperature dependence of mantle viscosity. Nevertheless, plate-tectonic motions with observed speeds of several cm/yr could not exist unless localized rheological weakening mechanisms (e.g., plasticity, grain-size reduction, partial melting) also operate, yielding interconnected linear

zones of weakness (i.e., plate boundaries) that continuously evolve in response to changing flow and stress distributions in the lithosphere and underlying mantle (e.g., Moresi and Solomatov 1998; Tackley 2000; Ghosh and Holt 2012; Rolf et al. 2018; Coltice et al. 2019). A rheological weakening mechanism that has been extensively employed to simulate plate boundary creation and evolution is viscoplasticity (e.g., Moresi and Solomatov 1998; Karato and Barbot 2018). The effective viscosity, η_{eff} , representing the combined operation of diffusion/dislocation creep and viscoplastic weakening may be mathematically expressed as follows:

$$\eta_{eff} = \left(\eta_{cr}^{-1} + \eta_{pl}^{-1} \right)^{-1}, \quad \text{where } \eta_{pl} = \frac{\tau_y}{2\dot{\epsilon}_{II}} \quad (1)$$

in which η_{cr} is the Arrhenius temperature-dependent creep viscosity (e.g., Karato and Wu 1993) and η_{pl} is the viscoplastic viscosity that is defined in terms of a yield stress, τ_y , and the square root of the second invariant of the strain-rate tensor, $\dot{\epsilon}_{II}$ (e.g., Moresi and Solomatov 1998). Expression (1) implies that when η_{pl} is much smaller than η_{cr} , then the effective viscosity of the lithosphere will be locally dominated by viscoplastic weakening: $\eta_{eff} \approx \eta_{pl}$ (e.g., Spiegelman et al. 2016).

The strong rheological contrast between the lithosphere and the underlying mantle is often used as the basis for models of plate-driving forces that treat the lithospheric plates and their descending limbs (subducted slabs) under the oceanic trenches (Fig. 1a) separately from the mantle (Elsasser 1969; McKenzie 1969; Solomon and Sleep 1974; Harper 1975; Forsyth and Uyeda 1975; Richardson et al. 1976; Chapple and Tullis 1977; Richter 1977; Davies 1978; Bird et al. 2008). Alternatively, the oceanic lithosphere can be regarded as an integral part of the convecting mantle. In the latter case, the lithosphere is modelled as the upper thermal boundary layer of mantle convection, such that the heat transported across the deep mantle by rising and sinking convective flow is finally transmitted to the Earth's surface by vertical conduction in balance with horizontal advection of heat in the lithosphere (Turcotte and Oxburgh 1967; Jarvis and Peltier 1982). The vertical viscosity gradient across the lithospheric plates, from an effectively undeformable (high-viscosity) surface to a more deformable (low-viscosity) base, is therefore a consequence of the thermal boundary-layer structure of the lithosphere.

This boundary-layer model provides an alternative context for interpreting plate-driving forces, in which the horizontal motions of Earth's oceanic lithospheric plates (Fig. 1a) are directly coupled to, and driven by, the mantle convective circulation (Turcotte and Oxburgh 1967; Richter 1973; Jarvis and Peltier 1982; Davies 1988). The horizontal plate motions are thus understood to be coupled to the underlying mantle flow generated by descending and ascending thermal plumes

(Hager and O'Connell 1981; Forte and Peltier 1987, 1994; Ricard and Vigny 1989; Gable et al. 1991; Vigny et al. 1991; Lithgow-Bertelloni and Richards 1998; Becker and O'Connell 2001; Lowman et al. 2008; Forte et al. 2009).

Balance Between Buoyancy Forces and Viscous Dissipation

Two distinct approaches have therefore been adopted to develop models of plate-driving forces where, on the one hand, the plate-driving forces are analyzed separately from the dynamics of the underlying mantle and, on the other, the plate motions are modelled as an integral part of the convecting mantle. Both approaches must satisfy a fundamental constraint that expresses how work done by the body forces throughout the mantle is dissipated by the viscous deformation associated with the tectonic plate motions and flow in the underlying mantle.

A mathematical expression of the balance between buoyancy and dissipation (e.g., Malvern 1969) over the entire volume, V_m , of the mantle (including the lithosphere) is:

$$-\int_{V_m} u_r \delta \rho g_o dV = \int_{V_m} \tau_{ij} \epsilon_{ij} dV - \int_{S_d} t_i \Delta u_i dS \quad (2)$$

in which τ_{ij} and ϵ_{ij} are the deviatoric stress and strain-rate tensors, respectively, t_i is a traction vector acting on surfaces S_d across which there is a discontinuity in motion Δu_i , u_r is the vertical (radial) component of mantle flow, $\delta \rho$ are lateral perturbations in density, and g_o is the radial gravitational field. All indices i and j represent components in each of the three Cartesian coordinate directions, and repeated indices (in the terms on the right-hand side of Eq. 2) denote summation over all values (1–3) of the indices. The traction vector t_i acting on the discontinuity surface S_d depends on the deviatoric stress as follows: $t_i = \tau_{ij} n_j$, in which the n_j are the Cartesian components of the local normal vector on S_d . Although the motion along S_d is discontinuous, the traction t_i must be continuous by Newton's third law (equal and opposite actions and reactions).

The left-hand side of Eq. (2) is the (positive) rate of work done by the buoyancy forces $\delta \rho g_o$ where vertical flow occurs, as in hot plumes where $\delta \rho < 0$ & $u_r > 0$, and in cold descending slabs where $\delta \rho > 0$ & $u_r < 0$ (Fig. 1a). The first term on the right-hand side of Eq. (2) is the rate at which the energy released by the buoyancy forces is dissipated by the internal stresses as they continuously deform the mantle. Since the mantle rheology on plate-tectonic time scales is viscous, this energy dissipation is simply the viscous friction that converts mechanical work into heat. The second term on the right-hand side represents the rate of frictional dissipation of energy on internal discontinuity surfaces or faults, and

Plate-Driving Forces, Fig. 1 (a) Schematic illustration of forces acting on lithospheric plates. All plate-driving forces ultimately arise from the buoyancy forces in the convecting mantle, namely, the force F_p due to hotter and less dense upwelling plumes and the force F_s due to the colder and denser sinking slabs. These sublithospheric buoyancy forces generate the plate-driving forces F_{sp} (slab pull) and F_{rp} (ridge push). Whether the force F_{bs} (basal shear) is a plate-driving or plate-resisting force depends on the relationship of the surface plate velocity v_p to the underlying mantle flow velocity v_m (see main text for discussion). The purely resistive plate forces are F_{sr} (slab resistance), F_{cr} (collision resistance), and F_{tr} (transform resistance). The balance between the slab-normal force F_{sn} and the opposing normal force generated by mantle flow will control the trench rollback or retreat velocity v_t [Figure adapted and modified from Forsyth and Uyeda (1975)]. (b) The observed (green arrows) and predicted (blue arrows) present-day plate velocities, where the former are from the GEODVEL model (Argus et al. 2010) and the latter are obtained from a tomography-based model of mantle convection (Forte et al. 2015). The plate motions are with respect to a global No-Net-Rotation (NNR) frame of reference. The plate names are shown by the abbreviations in red font: AFR Africa, ANT

Antarctica, ARB Arabia, AUS Australia, CAR Caribbean, CCO Cocos, EUR Eurasia, IND India, JDF Juan de Fuca, NAM North America, NAZ Nazca, PAC Pacific, PHI Philippine, SAM South America, SCO Scotia. (c) A map of the second invariant of the strain-rate tensor ($\sqrt{\epsilon_{ij}\epsilon_{ij}/2}$) at the surface of the lithosphere predicted by the tomography-based mantle flow model employed in (b). (d) The mantle flow predicted at 250 km depth using the tomography-based convection model (Forte et al. 2015). The magenta arrows show the horizontal component of the predicted flow vector, and the color contours show the vertical component (scale at bottom). The blue arrows show the predicted surface plate motions from (b). (e) The horizontal traction vectors (magenta arrows) at 90 km depth (just below the mean depth of the lithosphere) exerted by the mantle flow predicted by the tomography-based convection model (Forte et al. 2015). The blue arrows show the predicted horizontal flow velocities at 90 km depth. Scale bars for vectors are at bottom. (f) A map of the drag coefficient D_b determined using the basal traction F_{bs} at 90 km depth, shown in (e), and the predicted surface plate motion v_p , shown in (b)

hence this term is only relevant in the upper mantle and especially the crust, where significant earthquake faulting occurs. Since the frictional tractions t_i will always oppose the discontinuous fault motion Δu_i , the integral over the fault surfaces S_d must be negative (e.g., Malvern 1969).

As noted above, a large number of models have evaluated the plate-driving forces by specifically focusing on the lithosphere itself, treated as distinct from the mantle. In this context, a buoyancy-dissipation balance analogous to Eq. (2) can be developed:

$$\begin{aligned} & - \int_{V_l} u_r \delta \rho g_o dV - \int_{S_l} [\delta P - \rho_o \delta \phi] u_i n_i dS \\ & + \int_{S_l} u_j \tau_{ji} n_i dS \\ & = \int_{V_l} \tau_{ij} \epsilon_{ij} dV - \int_{S_d} t_i \Delta u_i dS \end{aligned} \quad (3)$$

in which V_l represents the volume occupied by the lithospheric layer, S_l defines the lower surface of the lithosphere (where the local normal vector n_i is approximately pointing in the negative radial direction $-\hat{r}$), δP and $\rho_o \delta \phi$ are, respectively, the dynamic pressure field and self-gravitation force acting on the base of the lithosphere, and $\tau_{ji} n_i = t_j$ are the deviatoric shear tractions exerted on the base of the lithosphere by the underlying mantle flow.

If the lithosphere has a sufficiently high viscosity, owing to its relatively colder temperatures compared to the mantle, the deformation rate ϵ_{ij} in plate interiors may be assumed to be negligible. If this approximation is accepted, the first term on the right-hand side of Eq. (3) may be ignored, and the primary frictional dissipation of energy occurs on the fault surfaces S_d that define the boundaries of the plates. The vertical flow u_r in the lithospheric layer is weak, owing to the proximity of the upper bounding surface, and thus the work done by the tangential shear stresses exerted by mantle flow (third term on the left-hand side of Eq. 3) is approximately balanced by the frictional dissipation of energy on plate boundary weak zones (e.g., faults). Since the dissipation on the right-hand side of Eq. (3) is always positive, this implies the tangential stresses on the base of the lithosphere are, on average, acting in the direction of the flow and hence do positive work on lithosphere. These approximations illustrate how plate motions may be governed by a balance between basal shear stresses, acting as plate-driving forces, and resistance to motion along plate boundaries (e.g., Hanks 1977; Davies 1978).

Expressions (2) and (3) are obtained on the assumption that no external tangential stresses are applied to the upper and lower bounding surfaces of the mantle and that the local vertical flow vanishes on these bounding surfaces. Some models of plate-driving forces have employed prescribed

plate velocities as a boundary condition, thereby implying corresponding *externally* applied tangential stresses on the lithosphere. This external forcing is sometimes figuratively referred to as the “hand of God” (e.g., Karpychev and Fleitout 1996). To avoid the nonphysical possibility that such external stresses do work on the lithosphere and underlying mantle, the models should be formulated so that compensating surface stresses, generated by the flowing mantle, are able to precisely cancel the work of externally applied stresses (e.g., Hager and O’Connell 1981).

The principal idea that emerges from these general considerations of the plate-driving forces is that plate motions are produced by the buoyancy forces $\delta \rho g_o$ in the mantle (left-hand side of Eq. 2). Even when the focus is placed on the lithosphere itself, the contribution of the driving forces in the mantle is still present but “hidden” in the basal stresses that are exerted on the lithospheric plate (left-hand side of Eq. 3).

Plate-Driving Forces: Lithospheric Models

Formulating the detailed physical mechanisms by which the vertically directed buoyancy forces in the mantle ($\mathbf{F}_s$ and $\mathbf{F}_p$ in Fig. 1a) are ultimately expressed as horizontal forces acting on and driving the plates is the central challenge in developing models that predict realistic plate motions. The earliest models explored the dynamics of the lithosphere and its descent into the mantle under deep ocean trenches (e.g., Elsasser 1969, 1971; McKenzie 1969; Richter 1973), and they suggested that the negative buoyancy forces due to the cold lithospheric slabs entering the mantle ($\mathbf{F}_s$ in Fig. 1a) are the most efficient drivers of the observed tectonic plate motions.

These initial efforts set the stage for the subsequent development of *parametrized plate-force models* in which the forces driving the plate motions are represented by a limited number of discrete force vectors acting on the lithosphere (Fig. 1a). One of the most influential studies of the parametrized plate-force models was carried out by Forsyth and Uyeda (1975). The forces they considered are identified in Fig. 1a, and they include (1) the **slab-pull force** $\mathbf{F}_{sp} = \mathbf{F}_s \sin \phi$ acting in the down-dip direction where ϕ is the dip angle of the slab; (2) the **slab-resistance force** $\mathbf{F}_{sr}$ representing the opposing viscous shear stress acting on the sides of the descending slab; (3) the **collision-resistance force** $\mathbf{F}_{cr}$ representing the frictional stress acting on the upper surface of the slab as it slides past the fault surface of the shallow Benioff zone; (4) the **basal shear force** $\mathbf{F}_{bs}$ representing the tangential shear stress generated by the flowing mantle acting on the base of the lithospheric plates; (5) the **transform-resistance force** $\mathbf{F}_{tr}$ representing the frictional stresses acting on segments of the plate boundaries where there is a component of relative motion that is tangential to the boundary, such

as transform faults; and (6) the **ridge-push force** F_{rp} corresponding to the lateral force exerted on the divergent plate boundaries due to the dynamic pressure field that produces the topographic elevation of the mid-ocean ridges.

The orthogonal complement to the slab-pull force is the slab-normal force $F_{sn} = F_s \cos \phi$ (Fig. 1a). This force component was not considered in the evaluation of the plate-driving forces by Forsyth and Uyeda (1975), but the balance between this force and the opposing normal stress in the mantle will contribute to the retrograde motion (or “rollback”) of the trench (e.g., Elsasser 1971; Schellart 2008; Funicello et al. 2008) with the relative velocity v_r , illustrated in Fig. 1a.

The results obtained by Forsyth and Uyeda (1975), and earlier by Richter (1973), suggested that the balance of forces on subducting slabs is the primary control on plate motions, and this understanding has been subsequently reiterated through a long suite of published models (e.g., Lithgow-Bertelloni and Richards 1998; Conrad and Lithgow-Bertelloni 2004; Billen 2008; Funicello et al. 2008; Schellart 2008; Stadler et al. 2010) up to the present day (e.g., Rolf et al. 2018; Coltice et al. 2019).

A major source of uncertainty in the classic force-balance models of plate motions is the unknown relationship between the motion of the lithospheric plates v_p and the underlying mantle flow v_m (Fig. 1a) and hence the unknown local magnitude and direction of the basal shear force F_{bs} . The majority of models assumed the mantle is passive and that the flow below the lithosphere is entirely generated by the subducting slabs. This is equivalent to assuming that the ambient mantle temperature outside the sinking lithosphere is isothermal or adiabatic (e.g., McKenzie 1969; Hager and O’Connell 1981). For these passive-mantle models, the basal shear force acts in the opposite direction to the plate velocity and therefore opposes the plate-driving force provided by subduction. Recent global convection modelling of plate-like surface motions driven by subducting slabs (Coltice et al. 2019) indeed shows that most (in excess of 2/3 of the global surface area) of the sublithospheric mantle is passive and driven by the overlying plate motions.

The conclusions obtained from traditional force-balance modelling are nonunique and depend on which forces are assumed to be known. For example, whether basal shear forces contribute to driving or resisting the plate motions will depend on what forces (in Fig. 1a) are prescribed as known at the outset. In the study by Forsyth and Uyeda (1975), it was assumed that basal shear forces oppose the plate motions and have a direction that is antiparallel to the plate velocity. In contrast, Davies (1978) showed that if the frictional force F_{tr} acting on transform boundaries is assumed to be known in advance, on the basis of earthquake stress-drop data (Hanks 1977), then the basal shear force may act as a plate-driving force. The force balance considered by Davies

(1978) also showed that the collision-resistance force F_{cr} may strongly oppose the slab-pull force F_{sp} , greatly reducing its contribution as a plate-driving force. The significance of basal shear stresses as a plate-driving force has also been highlighted by Bird et al. (2008) who employed a finite-element model of the lithosphere that incorporates stress- and temperature-dependent viscosity as well as an explicit treatment of plate boundary faults. Ghosh and Holt (2012) similarly found that basal shear tractions generated by buoyancy-driven mantle flow are the primary drivers of surface lithospheric velocities and yield close matches to present-day plate motions. The latter model results (see also Rowley et al. 2016) showing the importance of sublithospheric basal tractions as active drivers of plate motions differ from models that show a mainly passive mantle entrained by overlying plates driven by subducting slabs (e.g., Coltice et al. 2019).

Plate-Driving Forces: Whole-Mantle Models

The popularity of parametrized plate-force models that focused on the lithosphere was based on the use of readily observed input variables derived from surface tectonics and observed plate velocities. Since the observed plate velocities were employed as an input, these models could not explain how the plate motions were generated by the internal dynamics of the mantle nor how they would evolve over time.

Hager and O’Connell (1981) introduced 3-D spherical, whole-mantle flow models that explicitly included the interaction of the moving lithospheric plates with the underlying mantle. Although these models employed the present-day plate velocities as input, they predicted the 3-D flow throughout the mantle driven by a global distribution of subducted slabs derived from seismic catalogues of earthquake hypocenters. With the advent, in the 1980s, of seismic tomographic imaging of lateral heterogeneity in the mantle, it became feasible to apply these whole-mantle flow calculations to explore the detailed connection between surface plate motions and the 3-D flow in the mantle generated by thermal convection (e.g., Forte and Peltier 1987; Ricard and Vigny 1989).

Seismic tomography provides the only direct in situ constraints on the 3-D lateral structure of the convecting mantle, and it thus provides a unique basis for developing realistic models of mantle flow that are no longer limited to an understanding of Earth dynamics derived only from surface observations. The models of mantle flow by Hager and O’Connell (1981) were therefore further extended in studies demonstrating that present-day plate motions can be successfully predicted by 3-D distributions of buoyancy forces derived from seismic tomography (e.g., Vigny et al. 1991; Forte and Peltier 1994; Becker and O’Connell 2001; Ghosh and Holt 2012; Forte et al. 2015). This confirmation that plate motions can be

predicted on the basis of stresses generated in the underlying mantle by a 3-D pattern of convection is a major step toward developing a complete understanding of the dynamics and temporal evolution of the mantle and lithosphere as a single, internally coupled system (e.g., Lithgow-Bertelloni and Richards 1998; Conrad and Lithgow-Bertelloni 2004; Lowman et al. 2008; Forte et al. 2009; Rowley et al. 2016; Rolf et al. 2018).

A tomography-based model of present-day mantle flow (Forte et al. 2015) illustrates the detailed relationship between the convective circulation in the mantle and surface plate velocities. The model incorporates coupling of viscous mantle flow to overlying plates whose motions are limited to rigid-body rotations. The buoyancy-driven plate velocities predicted by this model (Fig. 1b) match the observations well (explaining 97% of data variance). The predicted lithospheric strain rates (Fig. 1c) are characterized by values ranging from less than $3 \times 10^{-16} \text{ s}^{-1}$ in plate interiors to two orders of magnitude greater along plate boundaries. According to Eq. (1), plastic weakening would then predict viscosity reductions in plate boundary zones between one and two orders of magnitude. Below the lithosphere, in the underlying low-viscosity portion of the upper mantle referred to as the “asthenosphere,” the predicted flow velocities show significant deviations from the overlying plate motions, for example, under the western half of the North American plate and under the African plate (Fig. 1d). The lack of parallelism between the surface plate velocities and the upper-mantle flow circulation in the asthenosphere is a consequence of the complex 3-D distribution of buoyancy forces in the deep mantle that are not correlated with the surface plate geometry (e.g., subduction zones and mid-ocean ridges) in any straightforward manner. An important exception is the prediction of a mantle-wide upwelling centered directly below the East Pacific Rise (Rowley et al. 2016). The lack of parallelism between surface and sublithospheric motions is also a consequence of the strong viscosity reduction in the asthenosphere, which allows a partial decoupling between these two layers.

The complex local variations in basal shear force relative to the surface velocities show that a simple correlation between these two, as assumed in the parametrized plate-force models (e.g., Forsyth and Uyeda 1975), is not appropriate. The local correlation between basal stresses and lithospheric motions may be quantified in terms of a drag coefficient, which provides a measure of the extent to which sublithospheric mantle flow actively “drags” the overlying lithosphere or vice versa. Two possible representations for the local mantle drag coefficient are:

$$D_b = \mathbf{F}_{bs} \cdot \mathbf{v}_p / (|\mathbf{F}_{bs}| |\mathbf{v}_p|) \quad \text{or} \quad D_v = \frac{\mathbf{v}_m}{\mathbf{v}_p} \cos \theta - 1 \quad (4)$$

in which θ is the angular deviation between the sublithospheric velocity $\mathbf{v}_m$ and the overlying plate velocity $\mathbf{v}_p$

(Fig. 1a). The drag coefficients D_b and D_v are correlated, because the orientation and magnitude of the horizontal motions in the plates and sublithospheric mantle will determine the orientation and magnitude of the basal shear force $\mathbf{F}_{bs}$ (Fig. 1a). A simple 1-D analysis of purely horizontal flow shows that when the flow velocity increases with depth (i.e., the mantle “drags” the overlying plate), then both D_b and D_v will be positive. The coefficient D_v is closely related, but opposite in sign, to the drag coefficient defined in Coltice et al. (2019). The tomography-based flow prediction of plate motions (Fig. 1d, e) yields the local drag coefficient D_b shown in Fig. 1f. Positive mantle drag of the overlying plate motions occurs in 63% of the total surface area of the lithosphere. A similar calculation of D_v (not shown here) yields a positive mantle drag in 65% of the surface area. The theoretical convection-driven plate motions simulated in Coltice et al. (2019) yield positive mantle drag in 20 to 40% of the surface.

The tomography-based whole-mantle flow models thus suggest that basal shear forces generated by a fully 3-D pattern of mantle convection drive the motions of the overlying plates (e.g., Vigny et al. 1991; Forte and Peltier 1994; Becker and O’Connell 2001; Ghosh and Holt 2012; Forte et al. 2015). The role of the plates is not entirely passive, however, because their intrinsic rigidity allows them to partially resist (and hence mask) a significant fraction of the deeper mantle flow patterns (e.g., Ricard and Vigny 1989; Forte et al. 2015). Furthermore, the buoyancy forces associated with subducted lithosphere do contribute to the basal shear forces that drive the plates (e.g., Coltice et al. 2019). Indeed, the continuous descent of lithosphere into the mantle ultimately generates a global distribution of subducted slabs that provide the negative buoyancy force $\mathbf{F}_s$ (Fig. 1a).

Summary

Much progress has been achieved in our understanding of how mantle convection drives the surface plate motions since the earliest parametric force models were published over four decades ago. In particular, the increase and availability of high-performance computational resources over the past decade have permitted the development of global mantle convection simulations that incorporate increasingly Earth-like characteristics, including the strong lateral variations of viscosity needed to simulate plate-tectonic movements (e.g., Ghosh and Holt 2012; Rolf et al. 2018; Coltice et al. 2019). Furthermore, major improvements in seismic tomographic inversions for 3-D mantle structure have been incorporated into global models of mantle flow that yield very good matches to a wide suite of convection-related surface data, including the present-day plate motions (e.g., Forte et al. 2015).

The interpretation of the seismic tomography models is however imperfect because individual published tomography

models are derived from damped, smoothed inversions and they are nonunique. Moreover, the independent mineral physical modelling required to convert the seismic anomalies in the tomography models into corresponding density perturbations adds further uncertainties that may impact the reliability of the mantle flow predictions (e.g., Rowley et al. 2016). These outstanding challenges have led to the emergence of two contrasting views on how thermal convection in the mantle drives the tectonic plate motions. The long-held, predominant view is that the buoyancy forces due to subducted slabs are the primary drivers of surface plate motions (e.g., Richter 1973; Conrad and Lithgow-Bertelloni 2004). According to this view, the thermal evolution of the mantle is mainly controlled by cooling from above (i.e., subducting lithosphere), which occurs when the mantle heating is mainly internal, with little heat flux across the core-mantle boundary. In this case, the buoyancy flux associated with subducted slabs strongly dominates that of hot upwellings, and the slabs therefore determine the dynamics of surface lithospheric movements (e.g., Coltice et al. 2019).

The second view that originated with the earliest mantle convection models (e.g., Turcotte and Oxburgh 1967) and some subsequent models (e.g., Jarvis and Peltier 1982; Forte et al. 2015; Rowley et al. 2016) is that a combination of active hot upwellings (“plumes”) and subducted slabs is required to explain the surface lithospheric motions. For such upwellings to be dynamically significant, there must be a large heat flux across the core-mantle boundary (CMB) and a well-developed lower thermal boundary layer that can sustain the activity of these hot plumes (e.g., Glišović et al. 2012). Time-dependent convection modelling that integrates a mantle buoyancy distribution derived from global seismic tomography yields a constellation of strongly developed and long-lived hot upwellings that remain geographically stable in time and are sustained by a large CMB heat flux ranging between 13 and 20 Terawatts (Glišović and Forte 2015). These tomography-based convection models are characterized by a present-day buoyancy flux from hot upwellings (i.e., plumes) and cold downwellings (i.e., slabs) that are of equal magnitude, such that the hot upwellings provide a substantial contribution to plate-driving forces (e.g., Rowley et al. 2016). The issue of heat flux across the CMB thus occupies a central role in determining the dynamical contribution of mantle-wide hot upwellings on plate-driving forces. Independent constraints on this heat flux from other disciplines, such as mineral physics (e.g., Pozzo et al. 2012; Ohta et al. 2016), are important in addressing this debate.

Plates and Paleoreconstructions

Alan G. Smith
(Deceased)

Definition

The *lithosphere* is the outer rigid part of the Earth, forming a shell whose thickness may range up to about 200 km.

A *tectonic plate* is a part of the Earth's lithosphere that is bounded by active plate margins.

A present-day *plate margin* is a seismically active zone that cuts the lithosphere.

Conservative plate boundaries are plate boundaries that separate two plates that are sliding past one another along a *transform fault* (which must cut the lithosphere). *Divergent (extensional) plate boundaries* mark where the two plates are separating from one another, generally forming *passive (or Atlantic) continental margins* (though extension can also occur behind island arcs).

Convergent plate boundaries are located between a converging oceanic and continental plate forming an *active (Pacific) continental margin*, or between a converging oceanic plate and an island arc.

A *global paleoreconstruction* shows a reassembly of the major continents (and oceans) relative to one another at some time in the past. If the reassembly is made using ocean-floor spreading magnetic anomalies and fracture zones, and derives

the geographic poles from paleomagnetism, it is a *global paleomap*. If only the continents are depicted, it is a *global paleocontinental reconstruction (or map)*. If each continent is projected separately onto a global map frame (as in pre-Mesozoic maps) it is a *global composite reconstruction*.

A *paleo-plate reconstruction* is simply a paleoreconstruction that shows the plate boundaries of the time concerned, that is, ridges, trenches, and major transform faults.

Earthquakes and Plates

Earthquakes are caused by the catastrophic release of accumulated elastic strain. The strain accumulates as a result of differential movement between parts of the lithosphere. A map of earthquakes over the past 40 years or so shows that differential movement is generally confined to narrow

seismic zones, particularly in the oceans (Fig. 1). Elsewhere there is little or no seismicity, showing that most of the lithosphere is not undergoing differential motion and is therefore rigid. The present-day surface extent of a plate is marked by zones of active seismicity that show the plate boundaries.

Plate Compositions, Sizes, and Shapes

Plates are made up of *Lithosphere, Continental*, with a thickness that probably averages about 200 km (Priestley and McKenzie 2006), and *Lithosphere, Oceanic*, whose thickness varies from a small value at a mid-ocean ridge, where it is created, to about 100 km for old oceanic lithosphere (Stein and Stein 1992; Crosby et al. 2006). Most of the plates in the Pacific Ocean are almost entirely, or entirely, made of oceanic lithosphere, but other plates are made up of varying

Plates and Paleoreconstructions, Fig. 1 Present-day earthquakes and simplified map of the present-day plates. The Philippine plate is also known as the Philippine Sea plate. The plate boundary between Eurasia and North America in northeast Asia is poorly defined. Cylindrical equidistant world map showing land areas as *light gray*. Areas between 2000 m water depth and the coastline are *blue* (colored version) or *light gray* (monochrome version). Deeper oceanic areas are uncolored. Over 400,000 earthquakes are shown. In the colored map, the color code is: 0–10 km (79,478) *blue*; 10–35 km (168,263) *light blue*; 35–100 km (79,890) *green*; 100–200 km (47,056) *yellow-green*; 200–300 km (11,144) *yellow*; 300–400 km (3874) *orange-brown*; 400–500 km (4674) *red*; 500–600 km (8427) *magenta*; 600–700 km (2477) *deep magenta*; >700 km (4) *black*. The monochrome version shows earthquakes ranging from *light gray* (shallow) to *black* (deepest). The rainbow-colored areas in the Australasia, together with smaller areas

along the western coast of the Americas, indicate zones of seismic activity of increasing depth. The continuous *black* line is the plate network showing 14 plates, all labeled. It is unclear whether the Indo-Australian plate should be considered to be two plates with a boundary in the NW Indian Ocean. The plate margins in the oceans are very narrow and conform to ideal plate margins; those in the continents are much broader. In particular, the wide belt of active deformation in the Alpine-Himalayan belt shows that the deformation is not restricted to the narrow plate margin on the map between the African, Arabian, and Indo-Australian plates on the one hand, and the southern Eurasian plate on the other. Rigid plate tectonic descriptions of such areas may be inappropriate. (Copyright A. G. Smith). The earthquakes are those of magnitude 4 or greater listed in <http://earthquake.usgs.gov/earthquakes/eqarchives/epic/>

proportions of continental and oceanic lithosphere (Fig. 1). There are no wholly continental plates. The shapes of most plates are quite irregular, reflecting their past histories of growth and destruction.

Plate Tectonics

Plate tectonics describe the motions of the lithospheric plates and the effects they cause. It is now the major branch of terrestrial tectonics, which is the study of the origins of the large-scale structures of the Earth, particularly the lithosphere. The name tectonics is derived from the Greek word *tektonikos* (τεκτονικός) “pertaining to building.”

Plate Motions and Euler’s Theorem

Plates are rigid bodies that can move relative to one another in three ways: one, they can slide past one another; two, they can move away from one another; three, they can move toward one another.

According to a theorem attributed to Euler, the relative motion of two rigid bodies on a sphere can be described as a rotation about a line passing through the Earth’s center that cuts the Earth’s surface at a point known as the rotation pole. The pole will have a latitude, λ , and a longitude, φ , with the rotation that takes place in a given time given by θ (Fig. 2). To a good approximation the Earth is a sphere and tectonic plates are rigid. Thus the motion of one plate relative to another in a

given time interval is given by their Euler rotation (λ, φ, θ). λ varies from 90° N, the N pole, conventionally given the value of +90, to 90° S, the S pole, or – 90. Longitudes are positive measured E from the Greenwich meridian, conventionally taken as 0°, or as 360°. If measured W from the Greenwich meridian, the longitudes are negative. Maps showing the whole world run from 0° E to 360° E, or 0 to –360. They could also run from 180° W, that is, –180, to 180° E, or +180. The sign of the rotation θ is found by fixing one plate as a reference and determining whether the rotation moves the second plate in an anticlockwise direction when looking down on it – a positive rotation – or moves clockwise – a negative rotation. Changing the reference plate changes the sign of the rotation.

Sliding Motions

When plates slide past one another they neither create nor destroy lithosphere. They conserve the lithosphere and are described as conservative plate boundaries. On a sphere such boundaries are circular arcs forming what are known as transform faults as in the San Andreas fault. The Euler pole is the point at the center of the arc.

Divergent Motions

When a continent breaks up and the pieces move away from one another the motion is divergent. At first the margins of the continents-to-be are stretched, forming what will become passive continental margins, as in the East African Rift. Eventually the stretching reaches the stage where new ocean-floor has to form, as in the Red Sea or the Gulf of Aden. The Euler rotations for each stage are given by the rotations needed to bring the different markers (passive margins; anomalies of the same age) together.

Convergent Motions

The local motions between present-day converging plates can be found from the slip vectors of earthquakes. If the convergent margin is long enough it is also possible to use these motions to estimate the position of the Euler pole. However, the local motions and Euler poles for ancient plate margins are difficult to estimate. In favorable circumstances it is possible to calculate them from a plate circuit. For example, the Cenozoic motion along a convergent plate boundary between India and the rest of Eurasia can be calculated by successively summing the motions from Eurasia to North America, North America to Africa, and Africa to the Indo–Australian plate (Fig. 1). All of these motions are known from the ocean-floor

Plates and Paleoreconstructions, Fig. 2 The line ABC on a rigid body on the surface of a sphere (e.g., Earth) is moved to A'B'C' by a rotation through the angle θ , about the rotation axis. The rotation axis passes through the center of the Earth and cuts the surface at point P with geographic coordinates of latitude λ and longitude φ (not shown), leading to an Euler rotation of (λ, φ, θ). (Copyright A. G. Smith)

spreading patterns in the Atlantic and Indian Oceans. Their sum gives the required result. The absence of any Paleozoic and Precambrian ocean-floor means that the motions and Euler poles at all pre-Mesozoic convergent plate boundaries are highly uncertain.

Reference Frames

Three classes of reference frames are relevant to global reconstructions: any plate, the paleomagnetic reference frame, and that given by “hot-spots.”

Plates as Reference Frames

Any plate, large or small, that can be linked to all the other plates can be used as reference frame to make a global reassembly: there is nothing fundamental in the choice of a plate. These global reassemblies are not geographic maps because they do not show the geographic latitude and longitude of the time concerned. To turn a reassembly into a map one needs to know the position of the geographic pole at the time concerned, which is given by paleomagnetism.

Paleomagnetism as a Reference Frame

Over a period of several tens of thousands of years or more, the Earth’s magnetic field averages to what is known as a geocentric axisymmetric dipole field, or GADF. Virtually all paleomagnetic measurements use this field model to interpret the

results. The field is geocentric because it behaves as if it were at the Earth’s center; it is axisymmetric because the field is symmetric about the Earth’s spin (or rotation) axis; and it behaves like a bar magnet and is therefore a dipole. Such a field has a very simple relationship between the angle, I , known as the inclination that the lines of magnetic force make with the horizontal, and the latitude, λ , of the point of observation:

$$\tan I = 2 \tan \lambda, \quad (1)$$

where $\tan$ = tangent of the angle (I or λ).

As a plate moves, the latitude of a point on it changes and the orientation of the plate varies. Both these effects are recorded in the remanent magnetization – or *Paleomagnetism, Principles* – preserved in rocks. The actual position of the north magnetic pole at the time must lie along the line through the observation point that coincides with the direction of the declination. It is at a distance of $(90 - \lambda)$ degrees from the observation point along that line. Thus, in principle, paleomagnetic data can be used to reposition that plate at the time that the old magnetism was superimposed on the rocks.

The determination of the age and direction of magnetization in rocks becomes progressively more difficult as one goes back in time, but these problems will not be discussed here. However, any Mesozoic or Cenozoic global reassembly can be turned into a map by finding where the mean north magnetic pole lies on the reassembly and making that point the north geographic pole of the map (Smith et al. 1994). A map of Pangea just before break-up is shown in Fig. 3.

Although paleomagnetic measurements give the past latitude and orientation of a plate, they do not give its past longitude. Thus it is generally not possible to make a

Plates and Paleoreconstructions, Fig. 3 Mollweide projection of Pangea reassembled at the end of the Triassic period, ~200 Ma. The green areas are the present-day coastlines; the blue areas all lie above 2000 m water depth, showing the approximate present-day extent of the continental crust. The latitude-longitude grid is drawn at 30° and shows in particular the estimated position of the late Triassic equator. Pangea was assembled by the collision of the southern continents (Gondwana) with the northern continents (Laurasia). A large oceanic area, known as

the Tethys, separated southern Eurasia from northeast Gondwana. The distribution of continental fragments lying within the Tethys is uncertain, particularly that of China and adjacent areas (the large fragment lying east of Eurasia). Some continental slivers and/or island arcs off western North America are shown schematically. Several other slivers probably lay adjacent to other continental margins of Pangea, but no attempt has been made to depict them. (Copyright A. G. Smith)

paleoreconstruction from paleomagnetic measurements alone. However, paleo-longitude differences between any two points on different continents will be correctly given if the relative position of the two points has been determined via a plate tectonic circuit whose individual motions are known.

Hot-Spots as a Reference Frame

The origin of linear volcanic chains like the Hawaiian Islands has been attributed to the slow movement of a tectonic plate over a fixed deep plume of hot mantle, giving rise to “hot-spots” at the surface (Wilson 1963; Morgan 1981). A purely descriptive term for them is that they are examples of “large igneous provinces” created in the case of hot-spots by intense, generally basaltic, magnetism. From the point of view of making reconstructions they show an interesting property in that they move relative to one another at rates that are an order of magnitude slower than those of plates. Hot-spots have been used as a reference frame that is believed to provide longitudes as well as latitudes for a global reassembly, forming a so-called absolute reference frame (Duncan 1981; Müller et al. 1993). The paleomagnetic reference and hot-spots reference frames agree within the limits of error for much of Cenozoic time, then gradually diverge for reasons that are not clear (Livermore et al. 1983).

Paleoreconstructions

Paleoreconstructions attempt to show where the oceans and continents were in the geological past. That this is possible is due to several effects: (1) conservation of continental crust during plate motions; (2) the record of Mesozoic and Cenozoic continental separation in the intervening ocean-floor; and (3) the record of changes in continental latitude and orientation in *Paleomagnetism, Principles*.

Conservation of Continental Shapes

The extension on passive continental margins is probably about 100 km for a margin that is 200 km wide at the present-day, such as parts of the eastern North American margin (e.g., Sawyer 1985). In other areas, the extension may be much higher: Powell et al. (1988) estimated a total of 360 km extension across the Australia–Antarctica margin before the formation of ocean-floor (180 km) equivalent to 1.6° of latitude for each margin, assuming symmetric extension.

To a good approximation, continental shapes on a global scale are conserved during plate motions. In detail this is clearly not the case. For example, when continents separate

the passive margins have been stretched. When two continents converge, the continental lithosphere of one continent overrides that of the other, which is then partially subducted. But because continental lithosphere is less dense than the underlying mantle, it cannot be subducted to any great depth. Thus the continental crust in the collisional zone becomes thickened and the area of continental crust decreases. In the case of the collision between India and Asia, the Tibetan plateau, and the Himalayas may represent a loss of continental area in a strip that may be more than 500 km wide (Coward et al. 1988; Shackleton 1988). As one goes back in time, the subducted Indian crust should be pulled out from under Eurasia and added to the Indian continent. Similar adjustments, but on a generally smaller scale, are necessary to the shapes of all continents caught up in collision zones, but are rarely made.

The continental shapes used for reconstructions generally show the edges of continents at about 2000 m water depth. This shape is unfamiliar where there is a wide shallow sea between the 2 km submarine bathymetry contour and the coastline. To aid in recognition, the present-day coastline is commonly shown on continents, but the coastline of the time concerned may be quite different, as well as being very difficult to pin down.

Record of Continental Separation in the Ocean-Floor

The ocean-floor generated during the break-up of Pangea and the creation of the Atlantic, India, Antarctic, and Arctic Oceans is still mostly preserved. Successively older oceanic transform faults, fracture zones, and ocean-floor magnetic anomalies and the continental edges themselves can be fitted together to give the Euler rotations needed to reposition all the major continents to a high degree of precision for most of Mesozoic and all of Cenozoic time, or roughly back to 200 Ma. The net results are paleocontinental reconstructions, that is, a display of the relative positions of the continents in the past (Smith et al. 1973).

Paleozoic and Precambrian Composites

For pre-Mesozoic time the only ocean-floor that remains is tectonically highly deformed. Thus Paleozoic and Precambrian global “maps” are made by geographically repositioning individual continents using paleomagnetism. The uncertainties in paleomagnetic poles are considerable, particularly for Precambrian time. Although the order in which the continents are arranged on the globe is known, at least for Paleozoic time, the longitude separations of adjacent continents are not. These separations are subjectively

estimated from evidence such as the distribution of fossils, tectonic effects, and the like. The results have been called composites, rather than maps, to emphasize the fact that they include qualitative data (Smith et al. 1973). The Precambrian has few fossils that provide an accurate indication of age and only scattered age determinations. Their absence, together with the absence of ocean-floor data and the uncertainties in pole positions, means that there are no generally agreed composites for most of Precambrian time. The Precambrian is still a veritable terra incognita.

Paleo-Plate Reconstructions

As noted above, a *global paleoreconstruction* is a reassembly of the major continents (and oceans) relative to one another at some time in the past. To turn this into a *paleo-plate reconstruction*, one needs to add the plate margins of the time concerned. For Jurassic and younger periods the former positions of ocean ridges are known from the ocean-floor record in the Atlantic, Indian, and Southern Oceans, but much of the Pacific ocean-floor has been subducted and for these areas former ridge positions have to be estimated. For Triassic and older periods the positions of former ocean ridges is largely a matter of informed guesswork (e.g., Stampfli and Borel 2002, 2004).

Orogenic belts, that is, those areas made up of deformed, metamorphosed, and igneous rocks, mark the former positions of convergent margins. However, the margins are commonly difficult to locate precisely and many orogenic belts include more than one former convergent margin, together with the locations of former oceans that have since been subducted. Thus although one can join former ridges to orogenic belts to make a sketch plate boundary map for the time concerned, this map is necessarily imprecise.

Precambrian *global paleoreconstructions* are generally schematic (e.g., Collins and Pisarevsky 2005). Because paleo-plate reconstructions build on an initial global reassembly, most Paleozoic and all Precambrian paleo-plate reconstructions are essentially cartoons that show the kinds of plate boundaries that may have existed at a given time but whose locations may have considerable errors.

Conclusions

The ocean-floor magnetic anomalies, transform faults, and fracture zones, together with the paleomagnetic frame allow very precise global Cenozoic and Mesozoic maps to be made. The inferred relative longitudes of Paleozoic and Precambrian continents depend on qualitative data, giving rise to poorly defined “composites.” Fossils enable precise dating of Paleozoic features that help in the construction of composites, but

such precision is not obtainable from Precambrian fossils, giving rise to considerable uncertainties in all Precambrian reconstructions. How to convert these global paleoreconstructions into verifiable paleo-plate reconstructions is a largely unsolved problem for pre-Mesozoic time.

Poroelasticity

Ran Bachrach

Geophysics and Planetary Sciences Department, Tel Aviv University, Tel Aviv, Israel

Definition

Poroelasticity is a joint formulation for the behavior of a solid–fluid coupled porous system. Poroelasticity describes the behavior of porous continuum and pore fluid with respect to applied displacements and stresses. Poroelasticity jointly treats the solid frame and pore fluid to calculate changes in pore pressure, solid displacements, and fluid displacements due to stresses and displacements associated with external or internal processes.

The theory of poroelasticity is based on the work of (Terzaghi 1941; Biot 1941, 1956a, b, 1962; Gassmann 1951). Poroelasticity is often called Biot theory as the work of M. A. Biot is considered to establish the complete foundation for the theory.

Basic Concepts

Consider a connected network of pores fully saturated with fluid. The following are basic concepts that form the basis for the theory of poroelasticity.

Drained and Undrained Deformation

For a fully saturated porous material, we consider two fundamental states (or thought experiments): *Drained* and *undrained* (sometimes these are called *jacketed* and *unjacketed* conditions).

Drained conditions are achieved when pore pressure in a representative elementary volume (REV) is in equilibrium with the surrounding throughout the deformation of the saturated porous medium. A special case (described as a lab experiment) is when pore pressure and fluid can freely diffuse

in and out of the sample during the deformation process. Undrained (or jacketed) conditions refer to the condition in which the boundary of the porous solid (REV) is impermeable and pore fluid cannot exit the rock during the deformation process.

Physical measurements on both states (laboratory measurements) will determine the poroelastic coefficients of the rock. Often “dry conditions” are associated with the drained experiment. In poroelasticity the term “dry” elastic modulus refers to the drained experiment and not the elastic modulus when the material is dry.

Linear Stress–Strain Formulation for Poroelastic Media

Consider the displacement vector in the solid $\mathbf{u} = [u_x, u_y, u_z]$ and the average fluid displacement vector in the pore space $\mathbf{U} = [U_x, U_y, U_z]$.

The volume of fluid displaced through a unit area normal to the x, y, z , direction is $\phi \mathbf{U}$ and the fluid displacement field is $\mathbf{w}$. The isotropic poroelastic stress–strain relations that relate stress, σ , and pore pressure, P , to displacement and strain, ϵ , can be written in an abbreviated notation as:

$$\begin{aligned}\sigma_{ij} &= 2\mu e_{ij} + \delta_{ij}(\lambda_c \theta - \alpha M \zeta) \\ P &= -\alpha M \theta + M \zeta \\ \theta &= \nabla \cdot \mathbf{u}, \zeta = \phi \nabla \cdot (\mathbf{u} - \mathbf{U})\end{aligned}$$

where λ_c is the lame’s coefficient for the closed (undrained) system and μ is the shear moduli. Note that the shear strain and stress are not affected by pore pressure and fluid presence. M , α are the two poroelastic constants associated with the poroelastic stress–strain formulation. M is known as Biot modulus, or P wave modulus, and relates dry response to saturated response as follows:

$$\begin{aligned}\lambda_c &= \lambda_{\text{dry}} + \alpha^2 M, \\ \frac{1}{M} &= \frac{\alpha - \phi}{K_0} + \frac{\phi}{K_f}.\end{aligned}$$

where K_f is the pore fluid bulk modulus and ϕ is the porosity. α is the Biot parameter and is defined as:

$$\alpha = 1 - K_{\text{dry}}/K_0$$

where K_{dry} is the bulk modulus of the rock measured under drained conditions and K_0 is the bulk modulus of the frame mineral.

Note that when the system is jacketed, that is, $\zeta = 0$ so there is no relative displacement between the fluid and matrix, the pore pressure and the total stress are related and the bulk modulus is defined in terms of “closed” elastic properties.

When the matrix is open, the assumption is that there is a constant pore pressure in the system (pore pressure is in

equilibrium with the surroundings) and thus fluid can flow freely in and out of the system. One special case of such conditions is when the pore pressure is equal to zero. The term “dry” frame conditions often refers to the states of zero pore pressure.

The poroelastic linear stress–strain relation can be written in terms of pore pressure as the coupling variable rather than the relative fluid displacement (or divergence). A popular form of the linear isotropic poroelastic stress–strain relations is given by:

$$\begin{aligned}\sigma_{ij} + \alpha P \delta_{ij} &= 2\mu e_{ij} + \lambda_{\text{dry}} \theta \delta_{ij} \\ \zeta &= (1/M)P + \alpha \theta\end{aligned}$$

Note that the pressure direction here is assumed to be negative, for example, the pore pressure resists a positive confining stress that pushes the grains together.

The above equation can be written as an equivalent linear elasticity relation by substituting the total stress with Biot effective stress $\sigma_{ij}^* = \sigma_{ij} + \alpha P \delta_{ij}$, as:

$$\begin{aligned}\sigma_{ij}^* &= 2\mu e_{ij} + \lambda_{\text{dry}} \theta \delta_{ij} \\ \zeta &= (1/M)P + \alpha \theta\end{aligned}$$

In terms of the differential pressure (also known as Terzaghi’s effective stress or just the “effective” stress) defined as $\sigma'_{ij} = \sigma_{ij} + P \delta_{ij}$ the linear stress–strain relations are given by:

$$\begin{aligned}\sigma'_{ij} - (1 - \alpha)P \delta_{ij} &= 2\mu e_{ij} + \lambda_{\text{dry}} \theta \delta_{ij} \\ \zeta &= (1/M)P + \alpha \theta\end{aligned}$$

When $\alpha = 1$ (soft materials where $K_{\text{dry}} \ll K_0$) the Biot effective stress is equal to the differential stress (often called Tarahzagi’s effective stress). Simple derivation of Biot’s effective stress law is given by Nur and Byerlee (1971).

Gassmann’s Equation and Fluid Substitution

Gassman’s equation (Gassmann 1951) relates the elastic constant of saturated material in closed or undrained state to the drained or open conditions. In its isotropic form, Gassmann’s equation can be written as:

$$\begin{aligned}\frac{K_{\text{sat}}}{K_0 - K_{\text{sat}}} &= \frac{K_{\text{dry}}}{K_0 - K_{\text{dry}}} + \frac{K_{fl}}{\varphi(K_0 - K_{fl})} \\ \mu_{\text{sat}} &= \mu_{\text{dry}}\end{aligned}$$

where K_{sat} refers to the saturated bulk modulus of the closed system. The shear modulus for the open system (dry) and the closed system are the same $\mu_{\text{sat}} = \mu_{\text{dry}}$ as fluid does not

contribute to the shear stiffness of the system. Gassmann’s equation can be derived directly from Biot’s equations or from basic elasticity considerations by accounting for mass conservation of pore fluid in a closed system. Gassmann’s equation assumes that pore fluid is in equilibrium throughout the sample and that the pore fluid does not interact with the mineral frame. For more information see Mavko et al. (1998). Anisotropic extension to Gassmann’s equation is derived by Brown and Korrington (1975) in terms of the elastic compliance tensor:

$$S_{ijkl}^{\text{dry}} - S_{ijkl}^{\text{sat}} = \frac{(S_{ij\alpha\alpha}^{\text{dry}} - S_{ij\alpha\alpha}^0)(S_{kl\alpha\alpha}^{\text{dry}} - S_{kl\alpha\alpha}^0)}{(S_{\alpha\alpha\beta\beta}^{\text{dry}} - S_{\alpha\alpha\beta\beta}^0) + (\beta_{fl} - \beta_0)}$$

where S_{ijkl}^{dry} , S_{ijkl}^{sat} are the saturated and dry 4th order compliance tensors, β_{fl} is the fluid compressibility (or inverse bulk modulus), and β_0 is the compressibility of the mineral frame.

Fluid Substitution

One of the many practical applications of Gassmann’s equation is the ability to predict the elastic modulus of a known rock saturated with different fluids. One example is the prediction of seismic velocity of a gas-saturated sediment given the seismic velocity of the same sediment saturated with brine. This fluid substitution scheme is readily derived from Gassmann’s equation:

$$\begin{aligned}\frac{K_{\text{sat}1}}{K_0 - K_{\text{sat}1}} - \frac{K_{fl1}}{\varphi(K_0 - K_{fl1})} &= \frac{K_{\text{sat}2}}{K_0 - K_{\text{sat}2}} - \frac{K_{fl2}}{\varphi(K_0 - K_{fl2})} \\ \mu_{\text{sat}2} &= \mu_{\text{sat}1}\end{aligned}$$

Skempton Coefficient

If the system is closed (jacketed), the pore pressure and the external stress are directly related as:

$$\begin{aligned}\theta &= \frac{(\bar{\sigma} - \alpha P)}{K_{\text{dry}}} \rightarrow P = \frac{1}{\alpha} (\bar{\sigma} - K_{\text{dry}} \theta), \bar{\sigma} = \sigma_{kk}/3 \\ \theta &= e_{kk} = \frac{\bar{\sigma}}{K_{\text{sat}}} \rightarrow P = \frac{1}{\alpha} (K_{\text{sat}} - K_{\text{dry}}) \theta \rightarrow P = B \bar{\sigma}, \\ B &= \frac{1}{K_{\text{sat}}} \left(\frac{K_{\text{sat}} - K_{\text{dry}}}{\alpha} \right)\end{aligned}$$

B is known as the Skempton coefficient and is one of the most measured laboratory quantity.

Three-Dimensional Consolidation

Poroelasticity provides the analytical framework for three dimensional consolidation of soils and sediments as follows:

Darcy's law relates fluid motion to pore pressure gradient and gradient of the gravitational potential G and can be written as

$$\partial \mathbf{w} / \partial t = \frac{-\boldsymbol{\kappa}}{\eta} \nabla P - \frac{-\boldsymbol{\kappa}}{\eta} \nabla G$$

where $\boldsymbol{\kappa}$ is the permeability tensor and η is the fluid viscosity.

The total stress field must satisfy the equilibrium equations (neglecting the inertia terms)

$$\sum \frac{\partial \sigma_{ij}}{\partial x_j} + \rho b_i = 0,$$

where b_i is the body force acting on the media (Gravity) and will be neglected in the following expressions. Combining Darcy's law with the equilibrium equation, we obtain the general consolidation equations that couple fluid and solid displacements of the vectors $\mathbf{u}$ and $\mathbf{w}$ as:

$$2 \sum_{ij} \frac{\partial}{\partial x_j} (\mu e_{ij}) + \frac{\partial}{\partial x_j} (\lambda_c \theta - \alpha M \zeta) = 0$$

$$\frac{\partial \mathbf{w}}{\partial t} = \frac{\boldsymbol{\kappa}}{\eta} \nabla (\alpha M \theta - M \zeta)$$

for the special case where the poroelastic coefficients are constant, the equation of motion is written (after application of the divergence operator and some algebra) as:

$$(2\mu + \lambda_c) \nabla^2 \theta - \alpha M \nabla^2 \zeta = 0$$

$$\frac{\partial \zeta}{\partial t} = \frac{\boldsymbol{\kappa}}{\eta} M_C \nabla^2 \zeta$$

$$M_C = M(2\mu + \lambda) / (2\mu + \lambda_c)$$

The latter equation can be written in terms of pore pressure as the familiar diffusion equation with an added volumetric solid deformation term:

$$\frac{\partial P}{\partial t} - \frac{\boldsymbol{\kappa}}{\eta} M \nabla^2 P = -\alpha M \frac{\partial \theta}{\partial t}$$

This equation is used extensively in the study of soil consolidation, compacting reservoirs, and stress–fluid coupled processes in the earth.

Dynamic Poroelasticity and Wave Propagation in Saturated Porous Medium

The wave equation in saturated porous media is derived by adding the inertia terms to the equation of motion. For

isotropic media with isotropic permeability, it can be written in terms of fluid and solid displacement vectors:

$$2 \sum_{ij} \frac{\partial}{\partial x_j} (\mu e_{ij}) + \frac{\partial}{\partial x_i} (\lambda_c \theta - \alpha M \zeta) = \frac{\partial^2}{\partial t^2} (\rho u_i + \rho_f w_i)$$

$$\frac{\partial}{\partial x_i} (\alpha M \theta - M \zeta) = \frac{\partial^2}{\partial t^2} (\rho_f u_i + m w_i) + \frac{\eta}{k} \frac{\partial w_i}{\partial t}$$

where $m = (\varphi \rho_f + \rho_a) / \varphi^2$ is the mass coupling parameters, and $\rho_a = \varphi \rho_f (a - 1)$ is the apparent density that relates the dynamic tortuosity to fluid density and rock porosity (Berryman 1980).

The equations of motion can be written in terms of rotation-free and dilatation-free equations similar to the equation for P and S wave in linear elasticity. However, unlike linear elasticity, in isotropic linear poroelastic media, there are two P waves that travel with two different velocities and a single shear wave velocity. The two P wave velocities are known as the fast and slow Biot wave velocities and have been observed in the laboratory (Plona 1980). When the fluid viscosity is zero, the two P waves are not attenuated but when the fluid viscosity is finite the slow Biot wave is highly attenuated and quickly decays into pore pressure diffusion. In his 1956 papers, Biot discusses many details associated with wave propagation in the low frequency range, which is the appropriate range for seismic investigation, and the high frequency range, which covers the ultrasonic case.

Definition

Dynamic elasticity allows predicting and explaining the propagation of perturbations in solids. The contributions of Newton, Hooke, Cauchy, and Navier laid the basis of dynamic elasticity by the beginnings of the nineteenth century. It is possible to solve the equation of motion in terms of displacements using potentials which are solutions of the wave equations for longitudinal (or compression) and transverse (or shear) waves. The waves that propagate in fluids like water and air are called acoustic waves. Plane waves are the simplest solutions of wave equation as discovered by D'Alembert. In conjunction with Fourier transforms, plane waves are central in the solutions of a variety of problems like waves in layered media and surface guided waves.

Summary

This entry deals with dynamic elasticity fundamentals. This theory is useful to explain the propagation of elastic waves in solids. Newton's second law allowed writing the equilibrium equation within an elastic medium. Cauchy developed the concept of stress and strain while Hooke's idea to relate linearly stress and strain led to Navier's equation which is in fact Newton's equation in terms of displacements. It can be solved using solutions of wave equations for P and S waves. Both static and dynamic elasticity were developed in the nineteenth century. However, the first synthetic seismogram was computed at the beginning of the twentieth century. Plane waves are the simplest solutions of wave equation and are a key component to study elastic wave propagation in layered media and surface waves. The Green's functions in time or frequency domain are the solutions for an impulsive or harmonic point load, respectively. The canonical case of an infinite homogeneous space is due to Stokes (1849) and is given here.

It has been recently discovered that the Green's function can be retrieved from averaging correlations of a diffuse field.

This applies for a very general medium. The relationship of energy and Green function allows establishing identities between average normalized measurements (correlations or autocorrelations) and intrinsic properties of the medium (imaginary part of Green function between two points or at the source itself) and opens the door to use noise measurements to construct virtual sources and do medium characterizations of unprecedented quality.

Introduction

Waves are part of our existence and manifest themselves at many scales and with an enormous variety of effects. Perhaps the most familiar waves could be those generated in a pond after a pebble is thrown. Other waves that we cannot see are the sound waves that propagate in the air. They allow both hearing and speech. Elastic waves are of the same type of acoustic waves but can be also of transverse nature as they can propagate in solids. In what follows we establish the fundamental equations and delineate solution strategies. Recent findings are pointed out.

Newton's Second Law

During the second half of seventeenth century Isaac Newton developed groundbreaking ideas of mechanics and optics; we can credit him the invention of calculus, although this has been a matter of bitter debate with Leibnitz and his followers. Regarding the motion of bodies, his descriptions enabled the industrial revolution. Consider a particle with mass m subjected to loads. Second Newton's Law establishes that:

$$\sum \mathbf{F} = m \mathbf{a}, \quad (1)$$

which means that the sum of forces equals the product of mass and acceleration. In this equation boldface letters represent vectors. For instance, the acceleration vector $\mathbf{a} = (a_1, a_2, a_3)^T$ has components a_j for the three directions x_j (with $j = 1, 2$, and 3). The upper index T means the transpose operation.

As velocity is the change of displacement with time, acceleration is the change of velocity with time. Therefore, acceleration is the second derivative of displacement $\mathbf{d}$ with respect to time and is written as:

$$\mathbf{a} = \frac{d^2 \mathbf{d}}{dt^2}. \quad (2)$$

Newtonian mechanics explained the motion of both celestial bodies and everyday objects. By means of the methods of calculus, developed significantly by Newton himself, these ideas were applied to deformable solids. For a successful

application, a relationship between forces and displacements, a constitutive law, is needed.

Cauchy's Stress and Strain

Assuming Cartesian coordinates and studying equilibrium within a continuum we can state Newton's second law per unit volume in modern form using both index notation and partial derivatives with respect to particular variables. In the index notation a repeated index implies summation. Thanks to the concept of stress tensor developed by Cauchy we can write the equations of equilibrium in the three Cartesian coordinates by means of:

$$\frac{\partial \sigma_{ji}}{\partial x_j} + f_i = \rho \frac{\partial^2 u_i}{\partial t^2}, \quad (3)$$

where $u_i(\mathbf{x}, t)$ = displacement vector of point $\mathbf{x}$ (represented by x_j , with $j = 1, 2$, and 3 , respectively, or by x, y , and z) and time t , $\sigma_{ji}(\mathbf{x}, t)$ = stress tensor components (force per unit area) on the faces of a particle oriented along the axis j (see Fig. 1), f_i = body force per unit volume, ρ = mass density, and the right-hand term is precisely the mass per unit volume multiplied by acceleration. Moreover, it is possible to show that in order to guarantee equilibrium on moments the stress tensor must be symmetric (i.e., $\sigma_{ji} = \sigma_{ij}$). The equilibrium at a given boundary subjected to tractions or forces per unit area leads to Cauchy equation $\sigma_{ij}n_j = t_i^{(n)}$ which relates the stress tensor at a point with traction associated to a given normal vector as depicted in Fig. 2.

The motion at point $\mathbf{x} + d\mathbf{x}$ allows for a first order description if it is within a small neighborhood of $\mathbf{x}$ and can be expressed in terms of values at $\mathbf{x}$ by means of:

$$\begin{aligned} u_i(\mathbf{x} + d\mathbf{x}, t) &= u_i(\mathbf{x}, t) + \frac{\partial u_i}{\partial x_k} dx_k \\ &= u_i(\mathbf{x}, t) + \frac{1}{2} \left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right) dx_k + \frac{1}{2} \\ &\quad \times \left(\frac{\partial u_i}{\partial x_k} - \frac{\partial u_k}{\partial x_i} \right) dx_k. \end{aligned} \quad (4)$$

The first and third terms of the last equality exhibit the motion at $\mathbf{x} + d\mathbf{x}$ as the composition of a rigid body translation and rotation, respectively, which do not produce any strains. The middle term really implies strains and is the product of the Cauchy infinitesimal strain tensor,

$$e_{ik} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right), \quad (5)$$

and the spatial differentials dx_k . This tensor is a natural candidate for a constitutive law.

Hooke's Law

Solids undergo deformations when subjected to loads. If deformations are small, a linear relationship can be assumed. This is what Robert Hooke did when studying springs. To secure his finding he even wrote an anagram: *ceiinossttuv* to hide the Latin sentence: *ut tensio sic vis* which literally means that the displacement (*vis*) is proportional to the force (*tensio*).

Nowadays, we express Hooke's law simply by writing $F = k \times \delta$ where F = force, k = spring constant or stiffness, and δ = displacement. Hooke and Newton were contemporary, but not very friendly to each other. Hooke claimed Newton stole him the notion of gravitational force as proportional to inverse square of distance; Newton ignored him. Actually, such an idea was implicit in Kepler's laws and many suspected it, but only Newton gave a precise quantitative account.

Propagation of Elastic Waves: Fundamentals, Fig. 1 Stress components on the faces of a particle oriented along the axes x, y , and z

Propagation of Elastic Waves: Fundamentals, Fig. 2 Traction vector on a plane with normal n_j

For linear elastic materials, the more general constitutive law is

$$\sigma_{ij} = c_{ijpq} e_{pq}. \quad (6)$$

This is Hooke's law expressing a linear relationship between stresses σ_{ij} and strain e_{pq} at a point. Very likely, Hooke never imagined such an extension. Technically speaking these are second-order tensors. Both are due to Cauchy.

Elastic properties appear in the tensor c_{ijpq} which is of fourth order. At a given point, it represents 81 entries, but after recognizing the symmetry of the stress and strain tensors, we have 36 independent constants. Energy considerations allow having only 21 constants for a general anisotropic solid. If the medium is isotropic we have

$$c_{ijpq} = \lambda \delta_{ij} \delta_{pq} + \mu (\delta_{ip} \delta_{jq} + \delta_{iq} \delta_{jp}), \quad (7)$$

where δ_{ij} = Kronecker delta ($=1$ if $i=j$; $=0$ if $i \neq j$; note that $\delta_{jj} = 3$) and the parameters λ, μ = Lamé constants. Equation 7 shows that only two independent constants are needed to describe a linear isotropic solid.

Navier's Equation

For isotropic materials, Hooke's law can be written as

$$\sigma_{ij} = \lambda e_{kk} \delta_{ij} + 2\mu e_{ij} \quad (8)$$

Substituting Eq. 8 in Eq. 3 and considering the definition of strain in Eq. 5, we can write the governing equation for motion within an elastic medium:

$$\mu \frac{\partial^2 u_i}{\partial x_j \partial x_j} + (\lambda + \mu) \frac{\partial^2 u_j}{\partial x_j \partial x_j} + f_i = \rho \frac{\partial^2 u_i}{\partial t^2}, \quad (9)$$

This is Navier's equation. It is possible to show that under very general circumstances the homogeneous solution (for $f_i = 0$) can be expressed by means of:

Propagation of Elastic Waves: Fundamentals, Fig. 3 Coordinate s along the vector $\mathbf{n}$. Line L corresponds to a constant value for s

$$u_i = \frac{\partial \phi}{\partial x_i} + \varepsilon_{ijk} \frac{\partial \psi_k}{\partial x_j} \text{ with } \frac{\partial \psi_k}{\partial x_k} = 0. \quad (10)$$

Here $\phi = \phi(\mathbf{x}, t)$ and $\psi_k = \psi_k(\mathbf{x}, t)$ are functions called potentials (see Achenbach 1973). The first is a scalar, while the second is a vector. These functions must be solutions of the homogeneous wave equations:

$$\frac{\partial^2 \phi}{\partial x_j \partial x_j} = \frac{1}{\alpha^2} \frac{\partial^2 \phi}{\partial t^2} \text{ and } \frac{\partial^2 \psi_k}{\partial x_j \partial x_j} = \frac{1}{\beta^2} \frac{\partial^2 \psi_k}{\partial t^2}, \quad (11)$$

respectively. This is supported by Lamé's theorem (for details see Aki and Richards 1980). Here $\alpha = \sqrt{(\lambda + 2\mu)/\rho}$ and $\beta = \sqrt{\mu/\rho}$ are the velocities of compressional (or P) and shear (or S) waves, respectively.

D'Alembert Solution of Wave Equation

For the linearly elastic, isotropic, homogeneous elastic medium, Navier's equation can be solved through the superposition of solutions of wave equation called potentials (see Aki and Richards 1980). Therefore, our capability to solve the canonical equation of dynamic elasticity rests upon the ability to solve the wave equation. This is subject of significant mathematical interest and many methods exist to look for solutions. Here we follow instead a quick, intuitive approach to solve the wave equation. In our opinion, the simplest solution is the one proposed by D'Alembert, a child of the French illustration of the eighteenth century. Extending his idea we can write

$$\phi(\mathbf{x}, t) = f\left(t - \frac{x_k n_k}{\alpha}\right) + g\left(t + \frac{x_k n_k}{\alpha}\right), \quad (12)$$

which is a solution of a wave equation for almost any function f and g , propagating along the unit vectors $\mathbf{n}_k$ and $-\mathbf{n}_k$, respectively. Equation 12 displays the beauty and power of D'Alembert solution. One powerful strategy is present in many methods and consists in sending explicitly plane waves in many directions.

This is what comes out after an exam of the arguments in Eq. 12. Consider that $x_k n_k = s$ is the equation of a plane in 3D space with a distance s from the origin, measured along $\mathbf{n}_k$. In vector notation we can write $\mathbf{x} \cdot \mathbf{n} = s$. This is the definition of a new coordinate s and is illustrated using the Cartesian system in 2D depicted in Fig. 3. The line L corresponds to a constant value for s .

Fourier Transforms and Plane Waves

In order to describe and generalize the power of the plane wave concept, consider the representation of a function

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \exp(+i\omega t) d\omega, \quad (13)$$

where $F(\omega)$ = Fourier transform of $f(t)$ given by

$$F(\omega) = \int_{-\infty}^{\infty} f(t) \exp(-i\omega t) dt. \quad (14)$$

Equation 13 exhibits an arbitrary function in terms of continuous superposition of sines and cosines. This fundamental property can be practically exploited under the assumptions that signals are discrete and periodic. We have then a powerful tool: the Discrete Fourier Transform. Moreover, the Fast Fourier Transform (FFT) algorithm allows for efficient computation. With this powerful tool we are effectively holding infinity in our hands. As the variable t in Eq. 13 is a dummy variable, we can substitute it by the D'Alembert argument $(t-s/c)$. Therefore, it is possible to write

$$\begin{aligned} f(t-s/c) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \exp[+i\omega(t-s/c)] d\omega \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) \exp[-i\omega s/c] \exp[+i\omega t] d\omega. \end{aligned} \quad (15)$$

We first see D'Alembert argument at the complex exponential, but then the contribution of the plane wave is given by the transfer function that multiplies the Fourier transform of signal. Let us consider the following transfer function

$$\exp[-i\omega s/c] = \exp[-i(\omega/c)\mathbf{n} \cdot \mathbf{x}] = \exp[-i\mathbf{k} \cdot \mathbf{x}], \quad (16)$$

that represents a harmonic plane wave propagating and identify that the wave vector $\mathbf{k} = (\omega/c)\mathbf{n}$ that gives the direction of propagation of the plane wave, where $\mathbf{n}$ is a unit vector ($n_1^2 + n_2^2 + n_3^2 = 1$).

It is possible to extend the idea that the unit vector $\mathbf{n}$ may have complex values then we have inhomogeneous plane waves. As an example of the significant representation power of generalized plane waves, we can express a harmonic spherical wave as a superposition of both homogeneous and inhomogeneous plane waves using the Weyl integral (see Aki and Richards 1980):

$$\begin{aligned} \frac{1}{R} \exp\left(-i\omega \frac{R}{c}\right) &= \frac{1}{2\pi} \\ &\times \iint \frac{\exp(-ik_x x - ik_y y - \gamma|z|)}{\gamma} dk_x dk_y. \end{aligned} \quad (17)$$

Here $\gamma = \sqrt{\omega^2/c^2 - k_x^2 - k_y^2}$ with the sign chosen so that $\text{Re } \gamma > 0$ and $R = \sqrt{x^2 + y^2 + z^2}$. Plane waves are then building blocks to construct solutions for the half-space problems and layered media. They play a central role in seismology. Certainly, it is the success of a simple, yet profound idea.

Green's Function for Homogeneous Space

The Green's function is the displacement field produced within an elastic medium by a concentrated, impulsive unit load at a given point. For an infinite, homogeneous, isotropic, elastic medium Stokes found the analytical solution at the middle of the nineteenth century.

If the body force is a unit concentrated impulsive, it can be represented with Dirac's delta functions for space and time. Moreover, to specify the force direction, we add Kronecker delta δ_{ij} ($=1$ if $i=j$, $=0$ for $i \neq j$). Therefore, we can define $f_i \equiv \delta_{ij} \delta(|\mathbf{x} - \boldsymbol{\xi}|) \delta(t)$ and $u_i(\mathbf{x}, t) \equiv G_{ij}(\mathbf{x}, \boldsymbol{\xi}; t)$ = Green's function for the infinite elastic domain. It is the displacement in direction i at $\mathbf{x}$ when a unit impulse is applied in direction j at point $\boldsymbol{\xi}$.

The Green's function should satisfy Navier's equation, which can be written as

$$\begin{aligned} \mu \frac{\partial^2 G_{ij}}{\partial x_k \partial x_k} + (\lambda + \mu) \frac{\partial^2 G_{kj}}{\partial x_i \partial x_k} - \rho \frac{\partial^2 G_{ij}}{\partial t^2} \\ = -\delta_{ij} \delta(|\mathbf{x} - \boldsymbol{\xi}|) \delta(t). \end{aligned} \quad (18)$$

The solution of this problem is due to Stokes (1849) and can be expressed by means of

$$G_{ij}(\mathbf{x}, \boldsymbol{\xi}; t) = \frac{1}{4\pi\mu r} \{ f_1 \gamma_i \gamma_j + f_2 (\delta_{ij} - \gamma_i \gamma_j) \}, \quad (19)$$

where $r = |\mathbf{x} - \boldsymbol{\xi}| = \sqrt{(x_1 - \xi_1)^2 + (x_2 - \xi_2)^2 + (x_3 - \xi_3)^2}$ and $\gamma_j = (x_j - \xi_j)/r$ is the unit vector from $\boldsymbol{\xi}$ to $\mathbf{x}$. The functions f_1 and f_2 are given by

$$f_1(r, t) = \frac{\beta^2}{\alpha^2} \delta(t - r/\alpha) + 2\beta^2 \int_{1/\alpha}^{1/\beta} \delta(t - r\kappa) \kappa d\kappa, \quad (20)$$

and

$$f_2(r, t) = \delta(t - r/\beta) - \beta^2 \int_{1/\alpha}^{1/\beta} \delta(t - \kappa r) \kappa d\kappa. \quad (21)$$

We notice in Eq. 19 that Stokes' (1849) solution decays as $1/r$ and is modulated angularly by sines and cosines. This solution clearly shows up the emergence of both dilatational and distortional (P and S) spherical waves with their characteristic radiation patterns. Equations 20 and 21 show that both the dominant P and S pulses share the time dependence with the source. The S pulse has a larger amplitude. Between these P and S arrivals we find a disturbance decaying more rapidly away from the source.

In the frequency domain (after applying Fourier transform) these functions can be written as follows:

$$f_1(r, \omega) = (\beta^2/\alpha^2) [1 - i2/q\alpha - 2/q^2 r^2] \exp(-iqr) + [i2/k\alpha + 2/k^2 r^2] \exp(-ikr), \quad (22)$$

and

$$f_2(r, \omega) = (\beta^2/\alpha^2) [i/q\alpha + 1/q^2 r^2] \exp(-iqr) + [1 - i/k\alpha - 1/k^2 r^2] \exp(-ikr). \quad (23)$$

Here $q = \omega/\alpha$ and $k = \omega/\beta$ are the wave numbers of P and S waves, respectively. If ω equals zero, the static case, we obtain the constants $f_1 = 1$ and $f_2 = (1 + \beta^2/\alpha^2)/2$ that correspond to the Kelvin solution for a unit static load in the full elastic space. The Stokes solution for the infinite space is frequently used in the integral BEM or IBEM formulations (see Bouchon and Sánchez-Sesma 2007). Other Green's functions in two and three dimensions can be used to solve a variety of problems. A remarkable compendium of fundamental solutions is the one due to Kausel (2006).

Fifty-five years after the Stokes' (1849) solution, at the eve of the twentieth century, Lamb (1904) found the solution for an impulsive vertical point load at the surface of a half-space. This solution is based on integral representations, and the passage to time domain became premonitory of methods developed some decades later. A complete account of Lamb's problem and summary can be found in Kausel (2013) who pointed out that the first truly complete solutions to Lamb's problem were obtained by Pekeris (1955) and Chao (1960). They provided closed-form expressions for displacements engendered by a vertical and a horizontal load, respectively, but only when Poisson's ratio is $1/4$. Significant advances are due to Mooney (1974) and Richards (1979). Sundry numerical computations of the Green's function associated to Lamb's problem are due to Johnson (1974). Explicit formulae have been recently given for the displacement at the

surface of an elastic half-space for a buried point source in what can be called the 3D Lamb's problem (Feng and Zhang 2018). Their results are expressed in terms of elementary algebraic expressions and elliptic integrals as well and are validated against Johnson's (1974) solution.

For a homogeneous or layered half space, the classical Fourier methods allow obtaining the elastodynamic Green's function in integral form. Typically, the fields constructed in each layer by a set of plane waves with unknown coefficients that are found after boundary conditions are enforced. The strategies to solve this problem are diverse and we count among them the global matrix approach (Knopoff 1964), the Thomson-Haskell method (Haskell 1953), the stiffness matrix (Kausel 2006), and the Kennett reflection-transmission method (Kennett 2001, 2002). The computation of the displacement and stress fields requires integration along the horizontal wavenumber domain. Usually, in the discrete wavenumber method (DWN) the horizontal wavenumber is discretized and Fourier analysis permits to go to time domain (see Bouchon and Aki 1977; Bouchon 2003).

Theory allows solving the problem of the homogeneous boundary conditions in terms of an eigenvalue problem. This led to the astounding subject of surface waves (See Aki and Richards 2002).

Green's Function Retrieval from Correlations

The pioneering studies of Aki (1957) on seismic ambient noise and coda are the basis of significant developments. Various scattering formulations have been developed in order to explain coda features (see Aki and Chouet 1975; Sato and Fehler 1998). When multiple scattering takes place, the intensities, which are related to energy densities, follow diffusion-like equations. These waves arrive at the receiver from different directions sampling the medium along their paths.

It has been found that the imaginary part of the elastodynamic Green's function is proportional to the average cross correlations within a diffuse field (for recent reviews, see Weaver 2010 and Perton and Sánchez-Sesma 2016). A diffuse field develops within a system if there is isotropic, equipartitioned illumination. One simple way to achieve this is using a set of elastic plane waves that fulfill the Principle of Equipartition (EQP) of Energy (Weaver 1982; Sánchez-Sesma and Campillo 2006; Sánchez-Sesma et al. 2006; Weaver 2010). On the other hand, simple illumination from isolated sources may give rise to diffuse fields after multiple scattering takes place (see Hennino et al. 2001; Paul et al. 2005).

The connection between this deterministic problem, namely, the computation of elastic Green's function and the

diffuse field theory, has been pointed out by Sánchez-Sesma et al. (2011a) in the framework of the partition of the energy injected into a half-space by surface loads (see Miller and Pursey 1955; Weaver 1985). In recent works, the computation of Green's functions for 2D layered systems was achieved using a cocktail of equipartitioned homogeneous plane waves (P , SV , SH) and surface waves (Rayleigh and Love). Pertion and Sánchez-Sesma (2016) discussed the case of a layered medium, while Baena-Rivera et al. (2016) considered an alluvial basin.

In reality, for elastic inhomogeneous, anisotropic, irregular medium the role of multiple scattering should be invoked to assert that under very general circumstances the resulting seismic ambient field is very likely diffuse. Under these circumstances, the Green's function can be approximately retrieved from averaging cross correlations of the recorded motions of such diffuse field (e.g., Weaver and Lobkis 2004; Wapenaar 2004; Gouédard et al. 2008).

Seismic noise is produced by nearby, superficial low strength sources that we will generically call microtremors. Noise sources are 3D in nature and have significant geometrical spreading. This attenuation make that the relative sampling of the medium in depth is also much reduced.

In what follows, we review the Green's function retrieval from correlations of field fluctuations. For the layered medium with free surface overlaying a half-space, we compute the imaginary part of the Green function when source and receiver coincide at the free surface.

It has been demonstrated (e.g., Sánchez-Sesma et al. 2008) that if a 3D diffuse harmonic displacement vector field $u_i(\mathbf{x}, \omega)$ is established within an elastic medium, the average cross-correlations of such motions at points $\mathbf{x}_A$ and $\mathbf{x}_B$ can be written as:

$$\langle u_i(\mathbf{x}_A, \omega) u_j^*(\mathbf{x}_B, \omega) \rangle = -2\pi E_S k^{-3} \text{Im}[G_{ij}(\mathbf{x}_A, \mathbf{x}_B, \omega)]. \quad (24)$$

In this equation, the Green's function $G_{ij}(\mathbf{x}_A, \mathbf{x}_B, \omega)$ = displacement at $\mathbf{x}_A$ in direction i produced by a unit harmonic point force acting at $\mathbf{x}_B$ in direction j , ω = circular frequency, $k = \omega/\beta$ = shear wavenumber, β = shear wave propagation velocity, and $E_S = \rho\omega^2 S^2$ = average energy density of shear waves (ρ = mass density, S^2 = average spectral density). Note that the asterisk implies the complex conjugate and the angular brackets mean azimuthal average. Equation 1 is the

Propagation of Elastic Waves: Fundamentals, Fig. 4 Correlations are computed with 20, 100, and 5000 sources, for the scalar case. We can see that as the number of sources considered increases the retrieval, the G_{22} function is better achieved

analytical consequence of a correlation-type elastic representation theorem and has been verified recently in canonical examples of a full space (Sánchez-Sesma and Campillo 2006) and for an elastic inclusion embedded in a full space and for more general circumstances (Sánchez-Sesma et al. 2006, 2008). For the scalar case it is possible to compare the Green's function retrieval from correlations. In Fig. 4, we show how the G_{22} function is retrieved taking into account 20, 100, and 5000 sources. The correlations are computed with these numbers of sources, and we can see that as the number of sources considered increases the retrieval is better achieved.

Energy Densities at Given Points and Directions

When source and receiver are both at the same point, we have interesting consequences. For each component the autocorrelation is proportional to the directional energy density (DED) at a given point. On the other hand, the imaginary part of the Green function at the source is finite because the singularity of the Green's function is restricted to the real part. Therefore, the DED is proportional to the imaginary part of Green's function.

In what follows we compute the theoretical energy density at a given point $\mathbf{x}_A$. In order to do so we rewrite Eq. 24 considering that $\mathbf{x}_A = \mathbf{x}_B$:

$$\begin{aligned} E(\mathbf{x}_A) &= \rho\omega^2 \langle u_m(\mathbf{x}_A) u_m^*(\mathbf{x}_A) \rangle \\ &= -2\pi\mu E_S k^{-1} \times \text{Im}[G_{mm}(\mathbf{x}_A, \mathbf{x}_A)] \end{aligned} \quad (25)$$

where μ = shear modulus. The energy density of shear waves E_S is a measure of the strength of the diffuse illumination. We see that the total energy density at a point is proportional to the imaginary part of the trace of the Green tensor for coincident receiver and source.

The imaginary part is finite and regular and represents the rate of energy injected by the unit harmonic load at that point. This quantity “detects” the energy that goes back to the source-receiver and may be used to imaging. Equation 25 is valid even if the summation convention is ignored. In that case $E(\mathbf{x}_A) \equiv E_m(\mathbf{x}_A)$ and the energy density is associated to a particular direction (for discussions see Pertion et al. 2009). The connection of the imaginary part of the Green's function at the source with the optical theorem has been explored by Snieder et al. (2009).

To illustrate these ideas from theoretical point of view, let us consider again the Stokes' (1849) solution. After applying Fourier transform to Eqs. 20 and 21 and taking the limit $r \rightarrow 0$, i.e., making that source and receiver coincide, we can write that

$$\text{Im}[G_{ij}(\mathbf{x}, \mathbf{x})] = -\frac{\omega}{12\pi\rho} \left(\frac{1}{\alpha^3} + \frac{2}{\beta^3} \right) \delta_{ij}. \quad (26)$$

This shows that the power injected into the infinite elastic medium by the unit harmonic load grows linearly with frequency, as expected, it is an isotropic tensor and the energy is explicitly labeled as being related to P and S waves follows the principle of equipartition.

The relationships among energy densities and its partitions have been studied by Pertion et al. (2009) for a half-space and by Margerin et al. (2009) for a stratified medium. The Green's function may be useful to imaging the subsurface structure at the site.

For horizontally layered systems and 1D excitation, the relationship between reflection response and autocorrelation of surface motion was discovered by Claerbout (1968). An algorithm to identify reflection coefficients based upon Claerbout's results was proposed by Scherbaum (1987). In fact, this is a single-station inversion method, and, in principle, it allows imaging of the subsurface impedance structure. The idea was tested using small local recorded earthquakes.

The Horizontal-to-Vertical Spectral Ratio

This concept, the duality of diffuse field energy density – medium impulse response or Green's function, is being the engine of practical applications in exploration geophysics and engineering seismology. Indeed, the microtremor H/V spectral ratio (MHVSR) is frequently used to assess the dominant frequency of soil sites. It requires to measure ground motion produced by seismic ambient noise at a site and the processing is relatively simple. The diffuse field theory asserts that the average autocorrelations of motion components of a diffuse field at a given receiver give the directional energy densities (DEDs) which are proportional to the imaginary parts of the Green's function components when source, receiver, and direction coincide. Therefore, the MHVSR can be modeled in terms of the Green's function, and this opens the door to inversion of medium properties in layered systems (see Sánchez-Sesma et al. 2011b; García-Jerez et al. 2016; Sánchez-Sesma 2017; Kawase et al. 2011, 2015; Lontsi et al. 2015, 2019) and systems with lateral heterogeneity as well (Matsushima et al. 2014, 2017).

Concluding Remarks

The fundamentals of dynamic elasticity have been reviewed. The Newton's second law and the Hooke's elastic idea led to the Navier-Cauchy governing equations. D'Alembert seminal solution in conjunction with Fourier analysis led to powerful descriptions in terms of plane waves. Dynamic elasticity is a

science with almost two centuries of history. It is alive with significant impacts in seismology and engineering. It is central in the theory and applications of diffuse field concept.

Radioactivity in Earth's Core

V. Rama Murthy
(Deceased)

Definition

Lithophile	Affinity for silicates
Chalcophile	Affinity for sulfur
Siderophile	Affinity for metals
BSE	Bulk Silicate Earth refers to primitive silicate material in the Earth from which the core is separated. Corresponds to the total mantle + crust system of silicates now.
P, T	Pressure, temperature
TW	Terawatt. $1 \text{ TW} = 10^{12} \text{ W}$
D_K	Concentration of K in Fe-alloy/ Concentration of K in silicate melt.
GPa	GigaPascal $= 10^9$ Pascals (1 GigaPascal is equivalent to 10 kilobars of pressure)
Geoneutrinos	Electron antineutrinos produced inside the Earth due to β^- decay of naturally occurring radioactive elements in the Earth.
Oxygen fugacity, f_{O_2}	A measure of the oxidation state of a system irrespective of the presence or absence of a gas phase containing free oxygen.
IW buffer	Iron–Wustite buffer. A synthetic redox mineral reference buffer representing the oxygen fugacity of a system where Fe_{metal} is in equilibrium with FeO (wustite), according to the reaction $\text{Fe}_{\text{metal}} + \frac{1}{2}\text{O}_2 = \text{FeO}$ (wustite). The IW buffer corresponds to $\log f_{O_2} = -12.5$ at $1,200^\circ\text{C}$.

Introduction

The Earth is a thermal engine driven by its internal heat. The bulk of this heat is produced by the elements potassium (K), uranium (U), and thorium (Th) through the radioactive decay of their isotopes ^{40}K , ^{235}U , ^{238}U , and ^{232}Th . Table 1 lists the atomic percentages, radioactive decay constants, half-life, and heat production characteristics of these radioactive isotopes.

Because K, U, and Th are strongly lithophile, differentiation of the Earth into a metallic core and a silicate primitive mantle (BSE) will have partitioned them overwhelmingly into the BSE. A long-standing convention is that the radioactivity of the BSE represents the total radioactivity of the Earth and that the metallic core has no radioactivity (e.g., McDonough 1999, 2003). However, radioactivity in the core has come into focus due to recent developments in three areas: (1) modern high P, T experiments on the metal-silicate partitioning behavior of K and U; (2) theoretical and experimental advances in our understanding of the electronic structure of potassium under conditions of high pressure and temperature; and (3) thermal models of the core that satisfy the size and age of the inner core and the energy to sustain geomagnetic field. Also, it is known that the heat due to radioactivity in BSE, about 19 TW (e.g., compiled in Lodders and Fegley 1998), falls short of the surface heat flux estimated at 30–44 TW (Lee 1970; Hofmeister and Criss 2005; Pollack et al. 1993). This shortfall is suggestive of either a higher than BSE radioactive content of the mantle and/or radioactivity in the core (see Murthy 2006). In the discussion below, new experimental developments are emphasized, citing where necessary the models and calculations that bear upon the radioactivity in the core.

Radioactivity in Earth's Core, Table 1 Important heat-producing radioactive isotopes in the Earth: atomic percentages, decay constants, half-lives, and heat production values. (After Van Schmus 1995)

Isotope	Atomic percentage	Decay constant λ (year ⁻¹)	Half-life (years)	Specific isotopic heat production (μWkg^{-1})
⁴⁰ K	0.01167	5.54×10^{-10}	1.251×10^9	29.17
²³⁵ U	0.7200	9.85×10^{-10}	7.038×10^8	568.7
²³⁸ U	99.2743	1.551×10^{-10}	4.468×10^9	94.65

Potassium Radioactivity in the Earth's Core

Potassium radioactivity in the Earth's core has been a topic of discussion for nearly four decades. Purely on geochemical grounds, Hall and Murthy (1971) and Lewis (1971) proposed that K enters the metallic core of the Earth as a consequence of the presence of sulfur in the core (Murthy and Hall 1970). Since then, the implications of K in the Earth's core for the energetics of the core, convection and core cooling rate, growth rate of the inner core, the geomagnetic field, and thermal evolution of the Earth have been noted in several studies (e.g., Verhoogen 1973; Goettel 1976; Gubbins et al. 1979; Stevenson et al. 1983). Early experiments, however, concluded against the presence of K in the core (Oversby and Ringwood 1972; Ganguly and Kennedy 1977; Murrell and Burnett 1986). These low pressure (1 bar to -1.5 GPa) and low temperature (1,030–1,350 °C) studies yielded very low distribution coefficients, D_K for potassium. The laboratory D_K values applied to core formation led to the conclusion that K cannot be present in an S-bearing core.

Since these first-generation experiments, we have made a substantial progress in understanding the partitioning behavior of elements. For example, we know now that the partitioning of an element between metal and silicate depends on a number of variables such as pressure, temperature, oxygen fugacity (fO_2), and the composition of both the metal and silicate melts (Murthy 1991; Hillgren et al. 1996; Jana and Walker 1997; Richter et al. 1997; Gessmann and Rubie 1998, 2000; Gessmann et al. 1999; Li and Agee 2001; Bouhifd and Jephcoat 2003; Chabot et al. 2005). In addition, core formation models suggest metal-silicate partitioning at a pressure range of 30–60 GPa and a temperature of 3,000–4,000 °C (e.g., see Rubie et al. 2003 and Chabot et al. 2005 and the discussion and references cited therein). In the context of these developments, several new experiments have investigated the possibility of K-radioactivity in the core.

Chabot and Drake (1999) made the first systematic study of the effect of some of the variables on K partition into metal alloys at 1.5 GPa and 1,900 °C. They showed that D_K was dependent on the S content of the metal alloy and on the composition of the silicate melt. Their experiments yielded low values of D_K ($\sim 6 \times 10^{-3}$) leading to their conclusion that the K content in an S-bearing metallic core will be trivially small (< 1 ppm). The D_K values obtained by Chabot and Drake (1999) are lower by an order of magnitude and at

variance with a number of later studies. This discrepancy may be due to their capsule choice (Gessman and Wood 2002) or due to other experimental artifacts caused by the extreme lability of K under experimental conditions (Murrell and Burnett 1986; Murthy et al. 2003).

Studies of K partitioning at high pressure and temperature (2.5–24 GPa and 1,500–1,900 °C) by Gessman and Wood (2002) found a significant entry of K into Fe-S-O alloys. K partition into the metallic liquids depended strongly on S and O contents of metal alloy and increased with temperature. K had little tendency to partition into S-free metal alloys, as was noted in many previous studies. They show clearly that the partitioning behavior of K is strongly influenced by anion/cation ratio of the Fe-sulfide liquid as well as the depolymerization level of the silicate liquid noted previously by Chabot and Drake (1999). Evaluating the effect of these and other variables on D_K , Gessman and Wood (2002) suggest the possibility of 100 ppm of K content in a core containing about 10% S and possibly up to a maximum of ~ 250 ppm for conditions relevant to core separation from a deep magma ocean.

Murthy et al. (2003) found a significant partition of K into Fe–FeS liquids in experiments at 1–3 GPa at temperatures above the liquidus of both metal and silicate phases (1,200–1,800 °C) and at $fO_2 \sim 1.5$ log units below IW buffer, corresponding to core separation conditions in a magma ocean (Walter and Thibault 1995; Chabot and Agee 2003; Chabot et al. 2005; Wade and Wood 2005). D_K seemed positively correlated with temperature as noted in previous studies but not correlated with pressure in the pressure range of the experiments. Extrapolating to deep magma ocean conditions and a core with $\sim 10\%$ S, the inferred K content is 60–130 ppm, a little lower but comparable to that inferred by Gessman and Wood (2002).

Bouhifd et al. (2007) studied the partition of K between silicates and FeS-rich alloy and pure Fe metal at 5–15 GPa and a temperature of 1,900 °C at an fO_2 between 1.5 and 3 log units below IW buffer. D_K was clearly positively correlated to S and O contents of the metal alloy and temperature as observed in previous experiments. In the pressure range of their experiments, no pressure dependence of D_K was observed both in sulfur-free and sulfur-bearing metal alloys. A parameterization of all existing D_K data showed a linear relationship between D_K and temperature, a relationship useful to predict D_K values at plausible

temperature relevant to core formation if the S and O contents of the core are known. For reasonable assumptions of S and O contents, Bouhifd et al. (2007) found K content of ~250 ppm in the core. If the core is free of S and O, the K content falls as low as ~25 ppm.

Partitioning experiments between peridotite silicate liquids and Fe-Ni-S-C-O melts at pressures of 1.0–7.7 GPa and temperatures of 1,650–2,200 °C by Corgne et al. (2007) did not find any relationship between D_K and temperature, as observed by Gessman and Wood (2002), Murthy et al. (2003), and Bouhifd et al. (2007). Nor did they find any dependence of D_K on the S content of metal alloy, as found in Chabot and Drake (1999), Gessman and Wood (2002), Murthy et al. (2003) and Bouhifd et al. (2007). A compositional control on D_K by the O content of the metal alloy was observed leading to their conclusion that a core containing S, C, and about 2 wt.% O could only have up to 25 ppm of K irrespective of the S and C levels. For a possible O content of ~5 wt.% (Badro et al. 2007), the K content of the core is ~80 ppm. However, the discrepancy between this work and the other recent studies is unresolved at present.

Quantum mechanical calculations predict a change in electronic structure of K at high pressures (from 4d-like orbitals to 3s-like orbitals), making K behave like a transition element (Bukowinski 1976; Lee et al. 2004). This prediction is experimentally confirmed by the work of Lee and Jeanloz (2003) that showed the alloying of K with a high-pressure polymorph of Fe at pressures >26 GPa and temperature 2,500 K. The change in chemical bonding behavior of K under pressure is noted in several other experiments (Ito et al. 1993; Parker et al. 1996; Hirao et al. 2006; Bouhifd et al. 2007). These experiments and calculations show that K entry into a Fe-metal core is facilitated by high temperatures and high pressures, making it siderophile at extreme conditions.

Radioactivity in the core is suggested in a number of studies concerned with the age and size of the inner core, and the energy required to sustain the geomagnetic field. The estimated core–mantle boundary (CMB) heat flux is 6–12 TW (Buffett 2003) and controls the rate of core cooling. Recent studies (Buffett 2003; Nimmo et al. 2004; Costin and Butler 2006) have examined the question of how best to reconcile the CMB heat flux with the size of inner core, the ~3.5 Ga history of the magnetic field, and the CMB temperature. These authors note that the presence of K in the core at ~200–400 ppm is in best accord with the present size of the inner core and the power needs of a geomagnetic dynamo. Using somewhat different parameters, similar conclusions have been reached by others (for example, Labrosse 2003; Buffett 2003; Butler et al. 2005; Costin and Butler 2006). Thus, it appears that a variety of thermal models of the core call for an additional heat source in the core. In view of the

recent experimental data, it is reasonable to attribute this at least in part to the radioactivity of K. However, no precise estimates are possible at present. A more definitive evaluation of the influence of temperature, pressure, and other variables on K partitioning into metal alloys is needed. There is also an uncertainty of the mantle K content at the time of core separation (Murthy 2006) although the convention is to use the model BSE content of ~240 ppm. Nor are the S and O contents of the core known. Given these caveats, a core K content of up to 250 ppm of K seems tenable. The corresponding radioactive heat production in the core, especially with any accompanying U and Th (see discussion below) would be ~2 TW, a significant fraction of the CMB heat flux. However, the uncertainty of these figures cannot be overemphasized. Table 2 summarizes the current estimates of K-radioactivity in the core from standard geochemical models, thermal modeling of the core, and recent high P, T partition experiments.

U (and Th) Radioactivity in the Earth's Core

There have been some attempts to evaluate the presence of U (and Th) in the core. Earlier experiments were largely at low pressure and low temperature. Furst et al. (1982) noted that under the highly reduced conditions relevant to core formation in the Earth, U and Th tend to become chalcophile (affinity for sulfur) and might enter a sulfur-bearing core. The chalcophile tendency of U under these conditions is confirmed by Murrell and Burnett (1986) and in the recent high P, T experiments described later. Feber et al. (1984) noted the significant solubility of UO_2 in impure Fe-metal at 1 bar pressure and at temperature $> 3,000$ K suggesting that significant U could be present in the core. In a series of detailed experiments, Murrell and Burnett (1986) measured the partitioning of K, U, and Th between silicate and sulfide liquids at low pressures (1 bar to 1.5 GPa) and found that U and Th tend to be less lithophile under reducing conditions and are markedly chalcophile and partition at greater levels than K into Fe–FeS liquids.

The high P, T partitioning experiments of U described below yield somewhat ambiguous results. Bao et al. (2005, 2006) investigated the partitioning of U between silicate melt and pure Fe liquids at pressures of 3.0–14.5 GPa and temperatures of 1,660–2,500 °C. They found that partition of U into the metal is dependent on whether the silicates were molten or solid and increases with both P and T. They found a similar P and T dependence of U in Fe-10 wt% S and Fe-35 wt% S liquids, with a positive dependence on S content of the metal phase. Inferred values for U content in core are in the range of 1–4 ppb for pure Fe and at least 10 ppb for 10 wt% S in core. At these latter levels, U alone can produce 1–2 TW of heat energy. Together with K, radioactivity in the core can then account for a significant fraction of the CMB heat flux. In contrast to these observations, Wheeler et al. (2006) found that U entry into core is not supported in their experiments for conditions up to 10 GPa, 2,300 °C and 28 wt% S at $f\text{O}_2$ about 2 log units below IW. The discrepancy between these two studies is not understood.

Malavergne et al. (2007) found that U partitioning into core metal is dependent on S content and highly reducing conditions ($f\text{O}_2$ about 4–5 log units below IW buffer) and at temperatures up to 2,400 °C and 20 GPa. These experiments permit a range of 0.0003–0.63 ppb U in core depending on whether the metal is S free or S rich. In experiments at temperatures of 2,200–2,400 °C and pressures up to 8 GPa, under very low oxygen fugacity (~ 4 log units below IW), Murthy et al. (2007) found U partitioning into metal to be positively correlated with S content. The data permit U concentration in the core of 1–2 ppb with a heat production of 0.1–0.3 TW.

In a series of papers, Herndon (see for example, Herndon 1998, 2006, and references to his work cited therein) has argued that gravitationally segregated U in the core functions

as a nuclear reactor to provide substantial energy. In order to segregate uranium into the core, the core–mantle differentiation needs to have occurred at $f\text{O}_2$ of about 4–5 log units below IW buffer (Malavergne et al. 2007). Such a scenario would have reduced most iron in the planet to metallic form, leaving little oxidized iron in the mantle. This is not supported by the fact that the mantle contains $\sim 8\%$ of oxidized iron. The mantle would also have been strongly depleted in Ta under such a low oxidation, which is not the case (Mann et al. 2009). Current ideas of core formation based on siderophile element partitioning in the mantle suggest a much higher oxygen fugacity of about 2 log units below IW. Schuiling (2006) discusses other difficulties of the Herndon proposal.

Conclusions

There have been many theoretical discussions of radioactivity in the Earth's core in the past. But it is the new high P, T experiments of metal-silicate partitioning of K and U that urge a serious consideration of radioactivity in the Earth's core. The experimental data could permit up to 250 ppm of K and up to 10 ppb of U in the core at the upper end. The corresponding heat production due to K and U (and associated Th) could be ~ 2 –4 TW, a significant fraction of the CMB heat flux. As mentioned in the section on K-radioactivity, the uncertainty in these numbers is very large. It may not be possible to precisely determine the radioactivity of the core by currently available geochemical and geophysical analyses except to note the general possibility of radioactivity in the core.

Away out of this impasse may now be available. Radioactive β^- decays of K, U, and Th in the interior of the Earth produce electron antineutrinos ($\bar{\nu}_e$).

These are termed geoneutrinos, and can serve as probes to directly measure the radioactivity of the Earth's mantle and core (e.g., Raghavan et al. 1998; Rothschild et al. 1998; Mantovani et al. 2004; Enomoto et al. 2005; Fiorentini et al. 2005; Giammarchi and Miramonti 2006). Geoneutrino flux measurements use the antineutrino inverse β -decay reaction with protons, $\bar{\nu}_e + p \rightarrow e^+ + n$ in an appropriate liquid in a scintillator chamber. The resulting positron and neutron emissions are then measured by usual scintillation techniques. Geoneutrinos from each radioactive isotope can be distinguished by their characteristic energy spectrum. Neutrino detectors exist now in several countries, and new ones less susceptible to interference by nuclear reactors and other near surface radioactive sources are planned. These developments in neutrino geophysics should be able to measure the U and Th abundances in the deep Earth and the core. Present detection techniques do not allow measurement of K due to the lower energy of its antineutrinos compared to those from U and Th decay. Further developments are needed for K determination. Geoneutrino measurements are likely to

provide a definitive answer about the level of radioactivity in the core and in addition clarify several questions regarding the Earth's formation, differentiation, chemical composition, heat budget, and geodynamics (Sleep 2006).

Radiogenic Heat Production in the Continental Crust

Claude Jaupart¹ and Jean-Claude Mareschal²

¹Université de Paris Institut de Physique du Globe, Paris, France

²Centre GEOTOP-UQAM, University of Québec, Montréal, QC, Canada

Definition

The crust is enriched in heat producing elements (HPE). Steady-state crustal temperature depends on Moho heat flux and the vertical distribution of HPE. Crustal differentiation with upper crustal enrichment in HPE cools and stabilizes the crust and makes it mechanically stronger.

Crustal Thickness and Heat Production

On a global average, radiogenic heat production in the continental crust accounts for about two-thirds of the surface heat flow in geological provinces that are in thermal equilibrium, that is, 30–40 mW m^{−2} over a total of 45–60 mW m^{−2} (Jaupart and Mareschal 2015). Save for a minor contribution from heat sources in the mantle lithosphere, the other component of the surface heat flow is heat supply from the convecting mantle. The key difference between these two components is in their time-dependence. The former (crustal heat production) decays with time due to the rundown of the

radioactive elements. The latter (mantle heat flux) does not vary much because continental lithosphere has remained thick over its whole history. As a consequence, the secular cooling of the mantle, which amounts to about 200 K over a total of 1600 K (see ► “Energy Budget of the Earth”), cannot induce large changes of heat flux at the base of the lithosphere. Thus, the secular evolution of the continental thermal structure is by and large a function of that of its crustal heat sources. This is consistent with the observed decrease of heat production with age (Fig. 1).

In steady state, the surface heat flux q_0 is the sum of the heat flux at the base of the crust q_m and the total crustal heat production.

$$q_0 = q_m + \int A(z)dz \quad (1)$$

with $A(z)$ the heat production. In stable continents, several independent methods indicate that the Moho heat flux lies within a narrow range of 12–18 mW m⁻² (Jaupart and Mareschal 2015), implying that variations of surface heat flux are mostly due to differences in crustal heat production. If the mantle heat flux q_m and the crustal thickness h_m can be determined independently, one can estimate the bulk average heat production of the crust, noted A_c , as follows:

Radiogenic Heat Production in the Continental Crust, Fig. 1 Average crustal heat production as a function of age, from Jaupart and Mareschal (2014). The large width of the age groups is due to the large spread of heat production values at any given age, which does not allow a fine scale separation. The curve illustrates the rundown of heat producing elements due to radioactive decay. After correction for this rundown, the crustal heat production at the time of crustal stabilization is essentially constant

$$A_c = \frac{\overline{q_0} - q_m}{h_m} \quad (2)$$

The thickness of the continental crust varies within a 20–60 km range (Fig. 2). Thus, assuming that the average crustal heat production is constant, one should observe large variations of the surface heat flux. This is clearly not the case (Fig. 3). For the global data sets, the total lack of correlation between heat flow and crustal thickness is partly due to transient thermal effects in tectonically perturbed provinces. A recent and accurate data set in the Precambrian Canadian Shield, which is in thermal steady-state, however, does not reveal any significant correlation between the two variables, implying that the thicker the crust, the lower the mean crustal heat production. One consequence is that one must determine the amount of crustal heat sources on a case-by-case basis. Calculating the total crustal heat production is relatively straightforward with sufficient surface heat flow coverage and even approximate knowledge of lithosphere thickness.

Crustal Differentiation

Constraining the vertical distribution of heat sources is fraught with a larger uncertainty than that for the average. Various estimates concur that heat producing elements are vertically differentiated with enrichment of the upper crust (Table 1).

From knowledge of the average value of heat production in surface rocks, A_s , one can calculate a “differentiation index” (Perry et al. 2006):

Radiogenic Heat Production in the Continental Crust, Fig. 2 Histogram of continental crust thicknesses sampled at 1° × 1° from Laske et al. (2013). Most of values >50 km or < 30 km are in active regions. μ and σ are the mean and standard deviation

Radiogenic Heat Production in the Continental Crust, Fig. 3 Scatter plot of heat flux and crustal thickness. (a) Global data set comparing heat flux averaged over $1^\circ \times 1^\circ$ cells vs. crustal thickness from CRUST1.0. The solid line represents the best linear “fit” to the cloud of points (with a correlation coefficient $r = -0.24$). (b) Data from eastern Canada. Heat flux data have been averaged over $1^\circ \times 1^\circ$ cells and their values are plotted against the corresponding crustal thickness values from Lithoprobe (Perry et al. 2002) and recent receiver function studies (Fiona Darbyshire, pers. comm.). The plot shows no significant trend and the correlation coefficient between the two data sets $r = 0.03$

$$D_I = \frac{A_S}{A_c} = \frac{A_S \times h_m}{\bar{q}_o - q_m} \quad (3)$$

where $\bar{q}_o$ is a regional average. D_I is equal to 1 if the crust is undifferentiated and is larger than 1 in most geological provinces because the upper crust is enriched compared to the bulk.

If the lower layer has zero heat production, an extreme case of differentiation, the upper layer thickness is:

$$h = \frac{h_m}{D_I} \quad (4)$$

and the crustal component of mantle temperature is:

$$\Delta T_c = \frac{1}{D_I} \frac{A_c h_m^2}{2\lambda} \quad (5)$$

with λ is thermal conductivity assumed constant.

A more general two-layer model has nonzero heat production in the lower layer and an upper layer of thickness $h \leq h_m/D_I$. In this case:

$$\Delta T_c = \frac{D_I A_c h^2}{2\lambda} + \left(\frac{A_c h_m (h_m + h)}{2\lambda} \right) \left(1 - \frac{D_I h}{h_m} \right) \quad (6)$$

This equation is useful to illustrate the effect of differentiation but precise calculations must include the temperature dependence of λ which may vary by a factor of 1.5 over the crustal temperature range. A value of $D_I > 1$ always results in lower value for the crustal component of Moho temperature than for an undifferentiated crust.

In general, values of D_I for different provinces are largest when heat flow is highest (Table 2). Values less than 1 are found in low heat flow subprovinces where the uppermost crustal layer has been emplaced tectonically.

Crustal Temperature and Strength

For a 40 km thick undifferentiated crust, lower crustal temperatures are near the melting temperature of the rocks at the time of crustal formation. Thermal stability of the crust can be achieved by crustal differentiation and remobilization of heat producing elements in the upper crust. For a differentiated crust, the temperature at the base of the crust increases with the thickness of the enriched layer h and decreases with increasing D_I , but the two parameters are not independent as shown by Eq. 3. In the lower crust, melting starts when temperature reaches $\approx 800^\circ \text{C}$. During the Archean with crustal heat production $\approx 1.5 \mu\text{W m}^{-3}$, lower crustal temperatures always exceeded melting conditions for a >40 km thick crust. But a crust up to 50 km thick could stay below melting if it is sufficiently differentiated ($D_I \geq 2$) (Fig. 4). The process is well illustrated for the Appalachians and the ca. 400 My Acadian orogeny, which saw the emplacement of enriched plutons in the upper crust both during and after the orogeny (Table 3). In this case, the present-day distribution of heat sources is not relevant to the Acadian thermal conditions.

parameters, lithospheric strength can be calculated and compared with potential energy difference. Such calculations show that: (1) for an undifferentiated crust with average crustal heat production, the lithosphere cannot withstand the stress of more than a few km crustal thickening, and (2) with increased D_I , the lithosphere can maintain greater differences in crustal thickness without collapsing (Fig. 5) (Jaupart et al. 2016).

Summary: Crustal Stabilization

In steady state, on average, temperatures in the continental crust increase with depth due to two heat flow components (crustal heat production and heat input from the mantle). It turns out that these two components account for about the same temperature rise at Moho depth. The influence of crustal heat sources is large in young provinces with high heat flow, and it happens to also be large in older ones when one accounts for radioactive decay. It also becomes large in continental collision zones with thickened crust. Over the time span of an orogenic event, 100 My, say, crustal heat production overwhelms the effect of magmatic intrusions, which are short-lived. Thus, thermal models of continents are very sensitive to crustal heat sources. In addition, the vertical distribution of crustal heat sources changes during orogenic events and is yet another variable which must be treated with care. A particularly important fact is that the distribution that is observed today is a consequence of orogeny and hence is not representative of conditions during the orogenic event itself. Usually, an orogenic event leads to the generation of crustal melts that rise toward the surface and leave a depleted residue. These processes act to generate a thermally stable and mechanically strong crust.

Radiogenic Heat Production in the Continental Crust, Fig. 5 Total strength of lithosphere vs. crustal thickness. The strength is calculated for $D_I = 1$ (undifferentiated) and $D_I = 2.5$ (differentiated crust). The potential energy difference relative to 40 km thick crust (ΔU) is given for comparison. (a) The average crustal heat production is $1.5 \mu\text{W m}^{-3}$ (i.e., the average heat production in cratons at the end of Archean). (b) The average crustal heat production is $1.1 \mu\text{W m}^{-3}$ (i.e., the average heat production of the Appalachians at the time of the Acadian orogeny)

Radiogenic Heat Production of Rocks

Christoph Clauser

Institute for Applied Geophysics and Geothermal Energy,
RWTH Aachen University, Aachen, Germany

Synonyms

Radiogenic heat generation rate

Definition

Radiogenic heat production	Physical property defining the amount of heat liberated in unit time in a unit volume of rock by the decay of unstable radiogenic isotopes; dimension: W m^{-3} .
Geoneutrino	An electron antineutrino emitted in β -decay of nuclei during radiogenic heat production caused by the decay of the unstable isotopes ^{238}U , ^{232}Th , and ^{40}K .
eV (electron Volt)	A non-SI unit of energy in nuclear physics, defined as the kinetic energy gained by an electron of elementary charge when accelerating through an electric potential difference of 1 V. Thus, one electron Volt equals one Volt, which is one Joule per Coulomb, multiplied by the electron charge of $e = 1.602176487(40) \times 10^{-19} \text{ C}$. Therefore, $1 \text{ eV} = 1.602176487 \times 10^{-19} \text{ J}$.
ppm (parts per million)	A non-SI unit of relative frequency (or abundance) in 10^{-6} , similar to % (percent) or ‰ (per mil) in 10^{-2} and 10^{-3} , respectively.

Radiogenic Heat Generation

The main interior sources of heat in the Earth are the heat content of the infant Earth immediately after formation due to gravitational contraction and the decay of unstable, radioactive isotopes. The potential energy released as heat during the gravitational accretion of the infant Earth dwarfs all other heat sources. This energy is calculated from gravitational contraction. The mass accumulated in a spheroidal planet of constant density ρ and radius r equals $m = (4\pi/3) r^3 \rho$. Addition of a further shell of thickness dr and mass $dm = 4\pi r^2 \rho dr$ results in the release of additional potential gravitational energy $dE_p = G m dm/r = (16/3) \pi^2 G \rho^2 r^4 dr$, where $G = 6673 \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$ is the universal gravitational constant. Integration yields:

$$E_p = \int_0^{r_E} dE_p = \int_0^{r_E} \frac{Gm}{r} dm = \frac{16\pi^2 \rho^2 G}{3} \int_0^{r_E} r^4 dr$$

$$= \frac{16\pi^2 \rho^2 G}{3} \frac{r^5}{5} = \underbrace{\left(\frac{4\pi r_E^3 \rho}{3} \right)^2}_{M_E} \frac{3G}{5r_E} = \frac{3}{5} \frac{GM_E^2}{r_E}, \quad (1)$$

where $M_E = 5.976 \times 10^{24} \text{ kg}$ and $r_E = 6.371 \times 10^6 \text{ m}$ are mass and radius of the Earth, respectively. Accordingly, the accretion of the Earth results in the release of heat on the order of $E_p = 2.24 \times 10^{32} \text{ J}$. A refined analysis considering the radial variation of density in the Earth modifies this value by only about 10 % to $E_p = 2.49 \times 10^{32} \text{ J}$ (Stacey and Davis 2008).

An additional, similarly large energy input is assumed to have occurred in the wake of an impact into the young infant Earth by a Mars-sized protoplanet orbiting the sun close to the Earth's orbit. The terrestrial Moon is generally believed to be the result of this impact, which released energy on the order of 10^{31} J (Melosh 1990; Canup and Righter 2000; Canup and Asphaug 2001). However, most of the vast energy liberated during accretion of the Earth or by this impact was radiated back into space already during accretion or immediately after the impact (Stacey and Davis 2008).

For an average specific heat capacity of $1.088 \text{ J kg}^{-1} \text{ K}^{-1}$ and a cooling by 650 K over a lifetime of 4.6 billion years, the mean rate by which the Earth is losing its original heat is 29 TW (Vacquier 1991, 1992). This corresponds to a thermal energy of $4.2 \times 10^{30} \text{ J}$. As the heat loss of the young and hot infant Earth was larger than today, the contribution of original heat to today's heat loss is certainly smaller. A larger cooling by 1175 K would result in a mean cooling rate of 52 TW corresponding to a thermal energy of $7.6 \times 10^{30} \text{ J}$ (Stacey and Davis 2008).

The annual production of radiogenic heat in the Earth, $6.3 \times 10^{20} \text{ J}$ (Jaupart et al. 2007), corresponds to more than twice the global production of primary energy in the year 2000. This huge energy source by itself clearly exceeds the world's energy annual demands predicted through the year 2030 (IEA 2008). If it were used at great scale, it may satisfy a large proportion of the primary energy demand of the entire twenty-first century.

Apart from the heat content of the infant Earth immediately after formation, the radiogenic decay of the unstable isotopes of uranium (^{238}U , ^{235}U), thorium (^{232}Th), and potassium (^{40}K) provides the largest internal source of heat. Most of these isotopes are enriched in the Earth's crust and mantle (Table 1). During radioactive decay, mass is converted into energy. Except for the tiny amount associated with the anti-neutrinos and neutrinos generated in β^- - and β^+ -decay or electron capture, respectively, all of this energy is converted into heat. Certain peaks in the corresponding γ -spectra are characteristic for the different decay series while the continuous background spectrum is due to Compton scattering and photoelectric absorption.

Radiogenic Heat Production of Rocks, Table 1 Average radiogenic heat generation rate per mass, A' , in geologic materials. (Data: McDonough and Sun 1995; Stacey and Davis 2008; Jaupart et al. 2007)

Material		Concentration (ppm by mass)				Heat generation rate (10^{-12} W kg $^{-1}$)
		C_U	C_{Th}	C_K	C_K/C_U	
Igneous rocks	Granites	4.6	18	33 000	7 000	1 050
	Alkali basalt	0.75	2.5	12 000	16 000	180
	Tholeiitic basalt	0.11	0.4	1 500	13 600	27
	Eclogite	0.035	0.15	500	14 000	9.2
	Peridotite, dunite	0.006	0.02	100	17 000	1.5
Meteorites	Carbonaceous chondrite	0.007 4–0.008 0	0.029–0.030	544–550	20 000	5.2
Moon	Apollo samples	0.23	0.85	590	2 500	47
Earth	Average crust (2.8×10^{22} kg)	1.2–1.3	4.5–5.6	15 500	13 000	293–330
	Average mantle (4.0×10^{24} kg)	0.013–0.025	0.040–0.087	70–160	2 800	2.8–5.1
	Average core	0	0	29	–	0.1
	Bulk silicate Earth (BSE)	$0.020 \pm 20\%$	$0.081 \pm 1.5\%$	$118 \pm 20\%$	5 400	4.7 ± 0.08

The two uranium isotopes, ^{238}U and ^{235}U , decay into lead, ^{206}Pb and ^{207}Pb , with a half-life of 4.5 and 0.71 billion years, respectively. Characteristic lines for the γ -spectrum of the ^{238}U decay series, for example, are produced by the daughter element bismuth, ^{214}Bi , at 609 keV, 1 120 keV, and 1 764 keV. Uranium is an abundant mobile trace element in many rocks. With a half-life of 14.1 billion years, thorium ^{232}Th decays also into lead ^{208}Pb . Characteristic lines for the γ -spectrum of the thorium decay series are produced by the daughter elements thallium, ^{208}Tl , or actinium, ^{228}Ac , at 584 keV and 2 615 keV or 912 keV and 966 keV, respectively. Thorium also occurs as a trace element, is relatively inactive chemically and frequently bound to clay minerals. The only unstable isotope of potassium is ^{40}K . It disintegrates by electron capture or emission into argon, ^{40}Ar , or calcium, ^{40}Ca , respectively, with a corresponding characteristic line in the γ -spectrum of the potassium decay at 1 460 keV. Potassium occurs in many clay minerals at concentrations of several percent.

Tabulated Data

The compilations of measured radiogenic heat generation rate which are reported in several research papers and reference books will not be duplicated here. Čermák and Rybach (1982) present a large collection of data arranged according to rock type. Van Schmus (1984, 1995) presents data on the abundance of radiogenic isotopes in various minerals and rocks of the Earth's crust and mantle and discusses the variation of radiogenic heat generation over the lifetime of the Earth. Stacey and Davis (2008) present data on average mass specific heat generation rates for various geologic materials, and Jaupart et al. (2007) discuss radiogenic heat sources in the Earth's crust and mantle. They provide an in-depth discussion on current models for the composition of a Bulk Silicate Earth (BSE), that is, the Earth's crust and mantle without the core: These are based on data from samples of either (1) meteorites considered

representative for the starting material and high-temperature processes in the early solar nebula when the Earth accreted or (2) upper mantle rocks formed by low-temperature processes. As can be expected, both show large variations in composition due to their different provenance and history.

Chondrites are considered representative of undifferentiated silicate material from the solar system prior to melting and the formation of a (mainly) iron core. Different classes of chondrites correspond to perturbations in elemental abundance in the gas state caused mainly by volatility or condensation temperature. The important elements with respect to radiogenic heat generation are uranium, thorium, and potassium. As elaborated by Jaupart et al. (2007), the first two condensate at very high temperature, why they are called 'refractory lithophile' elements. They show the same ratio in all types of chondritic meteorites, which demonstrates that they behave similarly in the early solar system. In contrast, potassium is a 'moderately volatile' element with a lower condensation temperature. The best agreement with solar concentration ratios is found for carbonaceous chondrites of the CI type of which, however, McDonough and Sun (1995) report only five finds. Compositional data exist only for three of them, in particular for the 700 g meteorite found near Ivuna in Tanzania in 1938 from which the name 'CI' is derived for this type of carbonaceous chondrite. However, chondrites are known to be more enriched in volatiles such as H_2O and CO_2 than the Earth.

A sample from the Earth's mantle is named "pyrolite," a contraction of the names of two principal mantle minerals, pyroxene and olivine, making up the complementary rocks peridotite and basalt. Because the former is the solid residue of the partial melting event which produced basalts, a mixture between the two was considered a suitable starting material, the pyrolytic mantle. Generally, pyrolite data suffer from leaching of uranium during low-temperature alteration. As most samples derive from the upper mantle, it has been questioned whether the pyrolytic composition adequately represents a bulk silicate Earth.

A third approach discussed by Jaupart et al. (2007) avoids a specific choice of a starting composition but determines it from the intersection of the two compositional trends of chondritic meteorites and peridotites. A source of error in this approach derives from the scatter in the two trends.

A fourth method proceeds from the elemental ratios of uranium and thorium and determines the primitive bulk Earth abundances from measurements on peridotites. Again, Jaupart et al. (2007) provide a concise introduction into this method. Table 1 summarizes mass-specific radiogenic heat generation rates for terrestrial rocks, meteorites, Moon surface samples, and average values for the Earth's crust, mantle, and a bulk silicate Earth (BSE).

Calculated Heat Generation Rate

The energy emitted by all of these decay processes comprises the kinetic energy of the emitted particles and the γ -radiation associated with the different decay processes. It is absorbed in the rocks and finally transformed into heat. In general, the total heat generation rate A of a rock is the sum of the individual contributions A_U , A_{Th} , and A_K by uranium, thorium, and potassium, respectively:

$$A = \rho(C_U A'_U + C_{Th} A'_{Th} + C_K A'_K), \quad (2)$$

where ρ is rock density, and A' and C are heat generation rate per mass and concentration, respectively, of the corresponding element in the rock. Table 2 shows values for A' reported by different authors. The variation is less than 3%, at most.

Thus, if a rock's density ρ and its concentrations in uranium (C_U), thorium (C_{Th}), and potassium (C_K) are known, its radiogenic heat generation rate A can be determined. Inserting the values, for example, of Rybach (1988) from Table 2 into Eq. 2 yields:

$$A(\mu W \text{ m}^{-3}) = 10^{-5} \times \rho(\text{kg m}^{-3}) \times \{9.52 \times C_U(\text{ppm}) + 2.56 \times C_{Th}(\text{ppm}) + 3.48 \times C_K(\%) \}, \quad (3)$$

where concentrations are given in weight-ppm (i.e., $10^{-6} \text{ kg kg}^{-1}$) for uranium and thorium and in weight-% for potassium.

The natural γ -radiation of rocks can be measured, for instance, by spectrometry on rock samples in the laboratory (see ► “Geomagnetic Field, Measurement Techniques”). An alternative source of γ -spectra is the natural gamma spectrometer (NGS) borehole tool which yields as output the three logs URAN (in weight-ppm uranium), THOR (in weight-ppm thorium), and POTA (in weight-% potassium). In combination with density RHOB from the compensated density log [g cm^{-3}], this information can be used directly to obtain the bulk heat generation rate A from Eq. 2 using any of the values for A'_U , A'_{Th} , and A'_K from Table 2.

Alternatively, for lack of spectra, the total γ -ray emission GR may be used, measured either in the laboratory or by suitable logging tools in boreholes. A γ -ray (GR) log is often included in most logging runs as one of the basic geophysical measurements in boreholes. Its reading reflects the combined radioactive decay of uranium, thorium, and potassium. However, it does not yield information on the individual contributions as it records the total number of γ -rays detected by the tool during a time interval. The relative gamma activities of uranium, thorium, and potassium, that is, the relative number of γ -rays emitted by the same mass during the same time interval are shown in Table 3.

Therefore, if POTA, THOR, and URAN are recorded as percent, ppm, and ppm, respectively, the gamma ray log's reading GR is proportional to the corresponding contents (Beardsmore and Cull 2001):

$$GR = X \times (POTA + 0.13 \times THOR + 0.36 \times URAN), \quad (4)$$

where the coefficient X varies with the radius of sensitivity of the log for detecting γ -rays. This varies with a number of factors, but lies within a few decimeters, at most, and can be approximated as constant for a given borehole (Beardsmore and Cull 2001). Then, bulk heat generation rate A can be related to GR by combining Eqs. 2 and 4 using the data of, for example, Rybach (1988) from Table 2:

$$\begin{aligned} \frac{A(\mu W \text{ m}^{-3})}{GR(\text{API})} &= 10^{-3} \times RHOB(\text{g cm}^{-3}) \frac{34.8 \times POTA(\%) + 25.6 \times THOR(\text{ppm}) + 95.2 \times URAN(\text{ppm})}{X(\text{API}) \times POTA(\%) + 0.13 \times THOR(\text{ppm}) + 0.36 \times URAN(\text{ppm})}, \\ \text{that is :} \\ A(\mu W \text{ m}^{-3}) &= 0.0348 \times RHOB(\text{g cm}^{-3}) \frac{GR(\text{API})}{X(\text{API})} \underbrace{\frac{POTA(\%) + 0.736 \times THOR(\text{ppm}) + 2.736 \times URAN(\text{ppm})}{POTA(\%) + 0.130 \times THOR(\text{ppm}) + 0.360 \times URAN(\text{ppm})}}_Y \\ &= 0.0348 \left(RHOB \times GR \times \frac{Y}{X} \right) \end{aligned} \quad (5)$$

Radiogenic Heat Production of Rocks, Table 2 Heat generation rate per mass, A' , for uranium, thorium, and potassium (Clauser 2009)

A'_U ($\mu\text{W kg}^{-1}$)	A'_{Th} ($\mu\text{W kg}^{-1}$)	A'_K ($\mu\text{W kg}^{-1}$)	Data source
97.0	27.0	0.0036	Birch (1954) cited in Jessop (1990)
97.7	26.3	0.0034	Hamza and Beck (1972) cited in Jessop (1990)
96.7	26.3	0.0035	Emsley (1989) and Jessop (1990) cited in Beardsmore and Cull (2001)
95.2	25.6	0.00348	Rybach (1988)

Radiogenic Heat Production of Rocks, Table 3 Relative gamma activity of uranium, thorium, and potassium. (Data source: Adams and Weaver (1958) and Emsley (1989) referred to in Beardsmore and Cull (2001))

Element	^{238}U	^{232}Th	^{40}K
Half-life (Ga)	4.47	14.1	1.28
Relative γ -activity	3 600	1 300	1

Y in Eq. 5 still contains the unknown relative elemental abundances. However, it turns out that the range for Y is limited between $1 \leq Y < 7.6$ for the two extreme cases when either $0 = \text{THOR} = \text{URAN}$ and $\text{POTA} > 0$, or $0 = \text{POTA} = \text{THOR}$ and $\text{URAN} > 0$. Beardsmore and Cull (2001) argue that in regions in which sediments have been derived from a common source through time the relative proportions of the elements in Eq. 5, and hence, Y should remain relatively constant with depth. Thus, Beardsmore and Cull (2001) maintain that a plot of A (derived, e.g., from a NGS log) versus $\text{RHOB} \times \text{GR}$ should yield a gradient, which depends only on the relative proportions of the radioactive elements in the sediments and should be similar over any region containing sediment derived from the same source.

An alternative empirical relationship was published by Bückner and Rybach (1996), which does not require information on the relative proportions of the radioactive elements in the rock. It relates bulk heat generation rate A to total γ -ray emission GR recorded by borehole tools as

$$A(\mu\text{W m}^{-3}) = 0.0158 \{ \text{GR}(\text{API}) - 0.8 \}. \quad (6)$$

This relation has been successfully tested on a number of data sets where both NGS and GR logs were available. As the relations in Eqs. 3 and 6 are based on measurements mostly on igneous rocks, caution is required when applying them to sedimentary rocks.

Measuring Techniques

A number of different analytical methods are available for determining the concentrations of uranium, thorium, and

potassium. An inter-laboratory comparison of different methods on selected materials yielded consistent results within a few percent (Rybach 1988). However, among all other methods, γ -ray spectroscopy is the only one which enables determining all three concentrations simultaneously. It implies secular equilibrium within the uranium and thorium decay series and a constant $^{40}\text{K}/\text{K}$ ratio, both of which are satisfied for most rock types (Rybach 1988). The method is based on counting the number of decays per energy channel. Commercial spectrometers will offer, for instance, 2048 channels for measuring decays in the energy range of 0 keV–3 000 keV, yielding a resolution, in this particular case, of 1.46 keV per channel. In performing measurements, it is important to realize that radioactive decay is a stochastic process. Therefore, decays need to be recorded over a sufficiently long time. In view of the minute uranium, thorium, and potassium concentrations, and depending on crystal size and sensitivity, this may imply recording times on the order of several hours. Additionally, a possible sampling bias needs to be considered when selecting samples for measurements.

The interpretation of γ -ray spectroscopy relates the elemental concentrations C linearly to the corresponding counting rates N in the energy channel x by the corresponding coefficient $h(x)$: $N(x) = h(x) C$. Thus, the total count rate due to the decay of uranium, thorium, and potassium in the energy channel x is given by:

$$N(x) = h_U(x) C_U(x) + h_{Th}(x) C_{Th}(x) + h_K(x) C_K. \quad (7)$$

The coefficients h depend mainly on the characteristic spectra of the radioactive elements, but also on the geometry of the sample, the geometric configuration of the measurement, and on the efficiency and sensitivity of the detectors. Thus, γ -spectroscopic measurements require calibration based on samples of known elemental concentrations. This enables accounting for the influence of the geometry of the detectors. Additionally, possibly variable sample geometry needs to be addressed separately. Three different effects require attention (Adams and Gasparini 1970): (1) *Variation of the continuous background spectrum* may occur if the background radiation was determined with an empty sample chamber in which no absorption of the natural background radiation occurs. This can be avoided by measuring the background radiation using a nonradioactive sample of equal size and similar density, such as water-filled plastic tubes; (2) *Deformation of the spectrum* may occur if a larger sample volume increases the likelihood for internal Compton scattering. Thus, larger samples are characterized by a decreased peak size and an increased level of the continuous spectrum; (3) *Radiation self-absorption* of a fraction of the γ -radiation emitted within the sample reduces the γ -radiation recorded at the detector. Self-absorption increases with sample thickness d and reduces the count rate N by a factor

$$F = \frac{1 - e^{-\mu d}}{\mu d}, \quad (8)$$

where μ is the absorption coefficient (Watt and Ramsden 1964). The joint effect of spectrum deformation and self-absorption is quantified by measurements on potash salt standards. While the absolute ^{40}K -concentrations are unknown, the relative variations reveal the influence of variable sample diameters. Theoretically, the total activity is proportional to the sample cross-section, that is, to the square of the sample diameter. In plotting the count rate versus sample diameter, one finds, however, a smaller exponent of only 1.5. Thus, the remainder of the radiation is either absorbed within the sample or transferred to other energy bands.

The energy peaks in the spectrum are analyzed for finding the elemental concentrations. Theory predicts a Gaussian normal distribution for the energy peaks. The count rate N at energy x in the local neighborhood of such a Gauß peak comprises a contribution of the Gauß peak itself, $G(x)$, and a linear trend $ax + b$, describing the background radiation and the Compton scattering (Adams and Gasparini 1970):

$$N(x) = G(x) + ax + b. \quad (9)$$

Such linear trends need to be removed prior to further interpretation, for example, by linear regression. Following this detrending the raw data need to be smoothed for further processing so that the energy peak's position can be clearly identified (Fig. 1). The area under the peak above the base line then corresponds to the sought total energy. In practice, the count rates within this area are summed up, or a Gaussian normal distribution function

$$G(x) = A e^{-(x-x_0)^2/2\sigma^2} \quad (10)$$

is fitted to the corrected peak, where x_0 and σ are mean energy and standard deviation of the peak, and A is a calibration constant. In a normal distribution, the peak's full width at half maximum (FWHM) is related to σ by

$$\text{FWHM} = 2\sigma\sqrt{\log_{10}(2)}. \quad (11)$$

The summed-up count rates analyzed this way then need to be calibrated by corresponding measurements on samples of known concentrations. Finally, this yields the concentrations of the radiogenic isotopes of uranium, thorium, and potassium.

Heat Generation and Geoneutrinos

Currently, general hypotheses on possible distributions of radiogenic heat generating elements in the mantle and core of the Earth are mainly based on analogies with chondritic material and direct evidence is lacking. However, as radiogenic sources produce heat, electron antineutrinos $\bar{\nu}$ are emitted in β^- -decay of nuclei in the decay chains of ^{238}U , ^{232}Th , and ^{40}K . Thus, the heat produced in nuclear decay is directly related to the antineutrino flux, as shown in Table 4 (Fiorentini et al. 2003).

Neutrinos are elementary particles that travel close to the speed of light, are electrically neutral, and can pass through ordinary matter almost undisturbed. They have a very small, but nonzero mass. Therefore, neutrinos are extremely difficult to detect. As the emission of geoneutrinos is coupled to radiogenic heat generation, this enables, at least theoretically,

Radiogenic Heat Production of Rocks, Fig. 1 Measurement and analysis of natural radioactivity shown here for the ^{214}Bi -peak at 609 keV; spectrum before (left) and after (right) removal of the linear base line trend (Eq. 10). FWHM computed after Eq. (11)

Radiogenic Heat Production of Rocks, Table 4 Maximum antineutrino energy and heat production rates in natural decay processes (de Meijer et al. 2006; Fiorentini et al. 2005)

Decay reaction	E_{max} (MeV)	Heat generation rate ($\mu\text{W kg}^{-1}$)
$^{238}\text{U} \rightarrow ^{206}\text{Pb} + 8\ ^4\text{He} + 6\ \text{e}^- + 6\ \bar{\nu}$	3.25	95
$^{232}\text{Th} \rightarrow ^{208}\text{Pb} + 6\ ^4\text{He} + 4\ \text{e}^- + 4\ \bar{\nu}$	2.25	27
$^{40}\text{K} \rightarrow ^{40}\text{Ca} + \text{e}^- + \bar{\nu}$	1.31	0.003 6

a geoneutrino tomography of radiogenic heat distribution within the Earth. But this concept is as difficult to implement as it is intriguing. First, there is a huge flux of cosmic neutrinos which traverses the Earth from which geoneutrinos need to be distinguished: The neutrino flux at the Earth’s surface from the sun alone is estimated at about $60 \times 10^9\ \text{s}^{-1}\ \text{cm}^{-2}$ (e.g., Bahcall 1969). The flux of geoneutrinos is three orders of magnitude smaller, but still on the order of $7.4(+2.1/-1.9) \times 10^6\ \text{s}^{-1}\ \text{cm}^{-2}$ (Kamland Collaboration 2011).

In spite of this immense flux density, the vanishing mass of neutrinos requires exceptional sensors for their detection: (1) At the Gran Sasso observatory in Italy, the detector is a tank of 100 t of liquid gallium trichloride (GaCl_3) containing the equivalent of 30 t of gallium at a subsurface laboratory. Here, antineutrinos are observed indirectly through the conversion of a gallium nucleus into a germanium isotope by neutrino capture. For all the high neutrino flux through the tank, an interaction of a neutrino and a gallium nucleus occurs only every 35 h. (2) In the *Kamioka Liquid Scintillator Antineutrino Detector (KamLAND)* experiment (Araki et al. 2005), the detector comprises of a 13 m diameter nylon balloon filled with 1 kt of liquid scintillator consisting of mineral oil, benzene, and fluorescent chemicals. KamLAND is an experiment at the Kamioka Observatory, an underground neutrino observatory near Toyama, Japan, built to detect electron antineutrinos. The experiment is located in the old Kamiokande cavity in a horizontal mine drift in the Japanese Alps. The detector is housed in an 18 m diameter stainless steel spherical vessel with 1879 photomultiplier tubes mounted on the inner surface. KamLAND is the first detector to conduct an investigation on geoneutrinos and may yield important geophysical information. It has the sensitivity to detect electron antineutrinos produced by the decay of ^{238}U and ^{232}Th within the Earth. Earth composition models suggest that the radiogenic power from these isotope decays is 16 TW, approximately half of the total measured heat dissipation rate from the Earth.

A successful antineutrino tomography requires global sampling and distinguishing between cosmic neutrinos traversing the Earth and geoneutrinos generated within the Earth. A project had been proposed some time ago (but unfortunately not funded) to deploy considerably smaller

neutrino detection sensors in a network of boreholes around the globe (de Meijer et al. 2006). Time will show whether the significant technical challenges associated with the construction of smaller sensors than those in the experiments at the Gran Sasso and Kamioka observatories can be overcome and a road opened for an antineutrino tomography of the Earth.

Summary

The heat produced in the radioactive decay of the unstable isotopes of uranium (^{238}U , ^{235}U), thorium (^{232}Th), and potassium (^{40}K) is the largest internal heat source of the Earth. During radioactive decay, mass is converted into energy. Except for the tiny amount associated with the antineutrino and neutrinos generated in β^- - and β^+ -decay or electron capture, respectively, all of this energy ends up as heat. The annual production of radiogenic heat in the Earth equals $8.6 \times 10^{20}\ \text{J}$, which is about 1½ times the global production of primary energy in the year 2017 (IEA 2020). The distribution of radiogenic isotopes in the Earth controls to a large extent the thermal regime of the Earth. Unfortunately, this distribution is known only with great uncertainty. Recently, it has become possible to detect geoneutrinos, that is, antineutrinos emitted during radioactive decay of unstable isotopes, in large detectors. With decreased size and improved accuracy of detectors together with directional resolution power, an antineutrino tomography of the Earth appears to become possible. Ideally, this would enable locating and quantifying the distribution of unstable isotopes in the Earth, thus helping to resolve a number of open questions with regard to the state and evolution of the Earth’s thermal regime.

Recovery of Source Magnetization Direction from Magnetic Field Data

Clive Foss

Mineral Resources, CSIRO, Lindfield, NSW, Australia

Definition

Magnetic field data are measurements of the strength, direction, or gradients of the magnetic field. Local variation between measurements is due to the external fields of nearby magnetizations. In favorable circumstances, the direction of those magnetizations can be estimated by analysis of magnetic field data.

Introduction

Most rocks at shallow depth in the earth contain ferromagnetic minerals with both induced and remanent magnetizations (see *Remanent Magnetism*). The inverse problem of determining the spatial distribution and magnetization of rocks from magnetic field analysis is a form of remote sensing with substantial challenges of non-uniqueness (see ► [“Inverse Theory, Linear”](#)). The direction of magnetization must either be known or be recovered as a part of the study. Induced magnetization is in most cases parallel to the local geomagnetic field. However, the strength of the induced magnetization is rarely known. For remanent magnetization, the strength and direction are also generally unknown. Remanent magnetization direction is of interest for age dating or correlation, global tectonic studies, and structural deformation investigations. It is also required to estimate the spatial distribution of magnetization. Analysis or inversion with an incorrect magnetization direction has long been recognized as a pitfall of magnetic field interpretation (see ► [“Magnetic Anomalies: Interpretation”](#)). A review of the many methods to estimate magnetization direction is provided by Clark (2014) and a review of the issues in deriving magnetization direction from magnetic field data is provided by Foss (2017).

The relative importance of induced and remanent magnetizations is traditionally quantified by the Koenigsberger ratio or “Q factor” (defined in Fig. 1) but this scalar statistic is insufficient to describe the vector relationship. Remanent magnetization parallel to the local geomagnetic field cannot be discriminated from induced magnetization by analysis of the static magnetic field, but also causes no error in estimation of the spatial distribution of magnetization. Many rocks contain some “soft” or “viscous” remanent magnetization in the present field direction carried by easily remagnetized

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 1 The vector relationship between remanent, induced, and resultant magnetizations

multidomain grains (see ► [“Magnetic Domains”](#)). The diagnostic expression of remanent magnetization in magnetic field data is best represented by the angle between the resultant magnetization and the geomagnetic field (the apparent resultant rotation angle or ARRA) as shown in Fig. 1. Angular difference between resultant magnetization and the geomagnetic field is caused by “hard” remanent components generally carried in single domain or pseudo-single domain grains. Many rocks have a large assemblage of magnetic mineral grains carrying both hard and soft remanent magnetizations. If the resultant rotation angle is large, the pattern of the external magnetic field of the magnetization will deviate substantially from that due to an equivalent distribution of induced magnetization suggesting the presence of remanent magnetization. However, additional information such as the Koenigsberger ratio or magnetic susceptibility value is still required to resolve remanent magnetization direction from the resultant magnetization. An alternative approach to dealing with complications due to unknown magnetization direction is to invert transforms which have low sensitivity to magnetization direction (Paine et al. 2001). This provides an approximate mapping of the distribution of magnetization but does not recover information about the magnetization direction. Lelièvre and Oldenburg (2009) developed a method to recover magnetization direction by inverting for three orthogonal components of magnetization.

The Expression of Magnetization Direction in Magnetic Field Data

For a thin planar (“2D”) distribution of magnetization, any components of magnetization in the strike direction of the sheet do not contribute to the magnetic field, and the angle of inclination of magnetization perpendicular to the sheet combines with the dip angle of the sheet into a single term from which neither can be independently recovered (Hood 1964).

This limitation led to an incorrect but widely and long-held assumption that magnetization direction cannot be reliably recovered from magnetic field data. However, Helbig (1963) proved that the magnetization direction of a dipole (a homogeneously magnetized sphere or a source so small that its shape is irrelevant) can be recovered from magnetic field analysis provided the dipole field is isolated from other fields and the horizontal center of magnetization is known. Schmidt and Clark (1998) recognized the potential for modern computing capabilities to apply Helbig’s analysis to recovery of magnetization direction from magnetic field data and their publication led to a switch in acceptance of the ability to recover magnetization estimates from magnetic field data.

In an early three-dimensional magnetic field modelling study (see ► [“Magnetic Modeling, Theory, and Computation”](#)) Zietz and Andreasen (1967) noted that in steep inclination geomagnetic fields the declination of magnetization of their source models is indicated by the peak to trough azimuth of the magnetic anomalies, and the inclination is indicated by the peak to trough amplitude ratios. These relationships are illustrated in Fig. 2 for steep northern and southern hemisphere fields. Shallow inclination magnetizations give rise to anomalies with similar peak and trough amplitudes; steep magnetizations parallel to the field (“normal”) give rise to predominantly positive anomalies, and magnetizations anti-parallel to the field (“reverse” – see ► [“Geomagnetic Field, Polarity Reversals”](#)) give rise to predominantly negative anomalies. In the southern hemisphere, the declination of magnetization is indicated by the trough to peak azimuth, and in the northern hemisphere by the peak to trough azimuth. A specified magnetization gives rise to a consistent external field, but as shown in Fig. 2 the total magnetic intensity (TMI) anomalies vary considerably in different geomagnetic settings because of their vector addition with those differently directed fields (see ► [“Geomagnetic Field, Global Pattern”](#)). Because we can recognize the expression of magnetization direction in magnetic anomaly patterns we should expect to recover magnetization directions by magnetic field analysis or inversion. To investigate recovery of magnetization direction, we can consider the three conditions for Helbig analysis; namely, correct isolation of the magnetic field due to the magnetization, knowledge or estimation of the center of magnetization, and the influence of the shape of distribution of the magnetization.

Magnetization Contrast and Anomaly Separation

The pattern of an anomaly depends on its isolation from background and other overlapping fields in what is known as “regional-residual separation” (see ► [“Magnetic Data Enhancements and Depth Estimation”](#)). Regional-residual

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 2 Dipole TMI anomalies of identical magnetizations in steep southern and northern geomagnetic fields

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 3 (a) TMI anomalies over holes in a volcanic sheet, (b) TMI computed from an inversion model of one of the holes, (c) the central section through the hole inversion model (shown in yellow)

separation is intrinsically interpretive and the output of any analytic method must be carefully checked. The choice of the regional field is also intrinsically related to the assumed background magnetization as illustrated in a study of magnetic field variations over part of the Beetaloo Basin of the Northern Territory of Australia (Foss and Dhu 2016) as shown in Fig. 3. This region is underlain by a wide volcanic

sheet delineated by a magnetic edge anomaly (beyond the area shown). The magnetic anomalies in Fig. 3 are interpreted as due to holes in the sheet; the background to each anomaly is the field above the sheet, and the direction of magnetization of the sheet is antiparallel to the magnetization derived from inversion of the hole anomalies. Because magnetic field anomalies are due to contrasts in magnetization and no

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 4 (a) TMI anomaly at Ethabuka, Queensland, Australia, (b) Standard RTP anomaly with borehole location, (c) RTP using the

inversion magnetization direction estimate. The top of the inversion model is outlined in magenta

absolute measure of the background field is available, it is not possible to reliably map the continuous distribution of magnetization beneath an area as is sometimes claimed of voxel inversion results. The moment integrals of Helbig analysis are particularly sensitive to error in anomaly separation but an approximate extension of Helbig's theory to analysis of tensor gradients provides significant advantage in isolation of the fields for analysis (Phillips et al. 2007).

Magnetization Direction and Source Location

Helbig analysis also requires supply of the horizontal center of magnetization. Inversion can seek to simultaneously recover estimates of magnetization direction and position but error in either of these parameters gives rise to error in the other. Alternatively, various magnetic field transforms can be used to estimate the center of magnetization. Figure 4a, b show a TMI anomaly measured at Ethabuka, Queensland, Australia, and the standard RTP transform as is commonly used to locate magnetic field anomalies above their source magnetizations. The TMI anomaly pattern is markedly different to that expected of an induced anomaly, disqualifying the assumption that magnetization is in the direction of the local geomagnetic field. A borehole into the RTP peak failed to intersect the magnetization. Parametric inversion of the anomaly recovered a model of low inclination southeast-directed magnetization (consistent with the magnetization and anomaly pattern relationships described above). The top of the inversion model plotted in Fig. 4b shows that the

proposed magnetization is not tested by the borehole. Figure 4c shows the compact, essentially positive anomaly of an amended RTP transform using the resultant magnetization direction of the inversion results. Correlation of gravity anomalies and RTP transforms can provide a test of magnetization direction for bodies with co-located density and magnetization contrasts, and correlation of RTP with source-centric transforms such as the total gradient can similarly investigate whether the magnetization direction is as assumed in the RTP transform (Roest and Pilkington 1993). Dannemiller and Li (2006) used correlation between total gradient and RTP with test magnetization directions to automatically select the preferred direction. The normalized source strength (Beiki et al. 2012) provides a similar and in some cases superior central function to the total gradient transform (see ► [“Magnetic Data Enhancements and Depth Estimation”](#)).

Magnetization Direction and Source Shape

Helbig analysis strictly applies only to a dipole magnetization which is at best an approximate representation of a geological body. As already noted, recovery of magnetization direction for thin sheet magnetizations is challenging and we can expect challenges arising from the shape of distribution of magnetization to progressively increase for magnetization distributions intermediate between a dipole and a sheet. Figure 5a shows a TMI anomaly at Coompana in South Australia and Fig. 5b shows four models of different

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 5 (a) the TMI northern anomaly at Coompana, South Australia with the center points of four alternative homogeneous magnetization models, (b) a perspective view of the models

geometry derived by inversions of the anomaly using independent forward modelling algorithms (Foss 2017). The computed fields of all the models closely match the measured field and all bodies are closely co-centered with near-identical resultant magnetization directions (Fig. 6a). Figure 6b shows a cross-plot of the volumes and intensity of magnetization of the models which both vary by a factor of 5, but their product (magnetic moment) values are consistent. These results reveal that for this body of magnetization and set of magnetic field data, estimates of the horizontal center of magnetization, mean magnetization direction, and magnetic moment are consistently recovered by inversion, but that the details of shape, intensity of magnetization, and volume are inconsistently estimated. The consistently recovered parameter values can be retained from any of the models with the models themselves discarded as improbable representations of the subsurface magnetization. Identical capabilities and limitations apply to voxel inversions. The consequence of

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 6 (a) A stereo net plot of the four inversion model magnetization directions, (b) a cross-plot of volume and intensity of magnetization for the four models with a single magnetic moment contour

departure of shape from that of a dipole can be approximately quantified by a term nominated as “compactness” which is the ratio of the closest approach of a field measurement location to the body of the maximum extent of the body. This simple statistic does not address the full complexity of three-dimensional shape, survey extent, and magnetization direction but importantly includes the influence of distance from source. At greater distances, the magnetic field of a body appears progressively more like that of a dipole. Alternatively, for a particular body of magnetization, measured magnetic fields can be classified as near-field or far-field (analogous to definitions of electro-magnetic fields due to an antenna) with magnetization direction most easily recovered from far-fields for which source shape is less significant. Fullagar and Pears (2015) developed methods to separately address the influence of shape and magnetization direction, but these methods require either independent constraints or assumptions.

Complex Distributions of Magnetization

Study of complex distributions of magnetization requires application of site-specific strategies. A complex magnetic anomaly of approximately 12 km diameter measured at Coompana, South Australia (Foss 2017), and shown in Fig. 7a appears to be due to magnetizations of more than one direction. Figure 7b shows a close match to the measured field forward computed from a multi-body, multi-magnetization inversion model. The NSS transform shown in Fig. 7c highlights the circular pattern of the anomaly and a small anomaly at its Centre. In a multistage inversion, it was surmised that the anomaly can be explained with four homogeneous magnetization bodies (bodies “a” to “d” in Fig. 8a). This starting model was then inverted with gradually increased degrees of freedom. Figure 8b shows a perspective view of the resulting model which has a consistent limited depth extent and slight inward plunge, suggesting that it might represent a high-level, subvolcanic intrusive complex. To provide a drillsite depth prediction, a separate, focused inversion was performed of only the center anomaly (Fig. 8c, d) which is too small to be properly constrained in the main inversion. The main bodies of magnetization provide the background field, and the inversion model is of an excess magnetization superimposed on those magnetizations (which are themselves superimposed). This inversion successfully predicted the intersection depth.

Homogeneity and Inhomogeneity of Magnetization

If it is not feasible to reliably resolve the distribution bounds of magnetization from inversion of a far-field anomaly, it is unlikely to be feasible to determine the internal homogeneity or inhomogeneity of that magnetization. This is illustrated by two studies of the northwest Black Hill Norite anomaly as shown in Fig. 9 from the Australian Remanent Anomalies Database (<http://bit.ly/2HvhZdP>). Figure 10a shows two magnetization models which both closely match the measured anomaly. One is a homogeneous magnetization (Foss and McKenzie 2011) and the other has the same three magnetizations in similar distribution as a model by Macleod and Ellis (2016). The magnetization directions of both models are plotted in Fig. 10b. The magnetization direction of the single magnetization model is only 11° from a remanence direction measured at a nearby outcrop (the body causing the anomaly is not itself exposed). It is further from the resultant magnetization at that site but the two bodies may have different Koenigsberger ratios. The mean magnetization direction of the triple magnetization model summed from each of its component parts is close to that of the single magnetization model and there is only a small difference in their total magnetization strength. From the existing magnetic field measurements, it is difficult to discriminate between the two models and establish whether the magnetization is

homogeneous or consists of three distinct components. However, in closer proximity (with near-field measurements) it might be possible to resolve individual magnetization directions for any inhomogeneities that may be present. Sun and Li (2019) propose an analysis for multiple magnetizations after first constructing a statistical model for the proposed number of magnetizations present.

Magnetic Field Studies and Paleomagnetism

The major restrictions in application of magnetic field analysis to palaeomagnetic studies are ambiguity in recovering remanent magnetization direction from resultant magnetization and inability to resolve different remanent components from the total remanent magnetization (NRM) as is achieved in palaeomagnetic studies through alternating field and

thermal demagnetization. There are, however, opportunities for integrating magnetic field and palaeomagnetic studies arising from their very different sample volumes. Palaeomagnetic studies directly measure remanent magnetization of small volumes, in many cases collected from limited locations. Magnetic field analysis can be used to test validity in ascribing palaeomagnetic results to much larger volumes than those directly sampled. Combination of palaeomagnetic studies from outcrop and magnetic field studies of deeper magnetizations unavailable for palaeomagnetic sampling can provide more complete mapping of the distribution of magnetizations. The usefulness of magnetic field studies for mapping the distribution of magnetization depends on the precision with which magnetization directions can be recovered (in favorable circumstances to within 10° or possibly even 5°) and will be significantly enhanced if high precision can be achieved by an automated search algorithm to enable

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 9 Australian Remanent Anomaly Database image of the northwest Black Hill Norite anomaly in the AUSGIN web portal

processing of large data sets. Possible remanent magnetization directions known from a defined apparent polar wander (APW) curve (see ► [“Paleomagnetism, Polar Wander”](#)) for an area can be used to guide inversion of magnetization direction (Cordani and Shukowsky 2009; Pratt et al. 2014). As a resource for both subsurface mineral exploration and palaeomagnetic studies, the Australian Remanent Anomalies Database (<http://bit.ly/2HvhZdP>) (see ► [“Magnetic Anomaly Map, Global”](#)) has been established to compile and distribute magnetic field magnetization results, and this national coverage can be extended using global scale datasets such as EMAG2 (doi: <https://doi.org/10.7289/V5H70CVX>). At the other extreme of spatial scales, micro mapping of magnetic fields over individual mineral grains provides information

about the genesis of specific magnetizations within palaeomagnetic samples (e.g. Pastore et al. 2019).

Conclusions

In favorable circumstances, estimates of magnetization direction can be recovered from analysis or inversion of magnetic field data. Analysis is best performed on fields of compact magnetization. Analysis of magnetic fields of planar sheet magnetizations is more problematic. Inversion of magnetic field measurements close to a magnetization depends on details of the distribution of that magnetization, but at increasing distance, the magnetic field progressively approximates to

Recovery of Source Magnetization Direction from Magnetic Field Data, Fig. 10 (a) alternative single and triple magnetization inversion models for the northwest Black Hill Norite anomaly, (b) stereonet display of the inversion model magnetizations

that of a dipole and inversion is simpler (provided that the lower amplitude distal field can still be reliably isolated). More complex distributions of magnetization can also be inverted, but only where fields of individual magnetization are at least partially separated, and generally with increased scope of non-uniqueness in the results. Magnetic field analysis provides estimates of resultant magnetization. Further information is required to resolve the resultant into induced and remanent components.

Remanent Magnetism

Laurie Brown¹ and Suzanne McEnroe²

¹Department of Geosciences, University of Massachusetts, Amherst, MA, USA

²Norwegian Geological Survey, Trondheim, Norway

Definition

Remanent magnetization Permanent magnetization held in rocks and other earth materials, commonly, though not always, dating from cooling to below the Curie temperature (T_c) or Néel temperature (T_n) of the magnetic minerals in the rock, or the time of formation of the rock unit.

Introduction

The fact that earth materials, particularly rocks, possess a permanent magnetization has been known for some time. Early observations of rocks producing large anomalies were commonly ascribed to lightning strikes. By the mid-nineteenth century remanence was accepted as a property of some rocks, and by the early twentieth century crude measurements of the direction of magnetization were possible. During the second half of the twentieth century, the measurement of remanent magnetization (RM) became a well-established research field (see entries under ► “[Paleomagnetism, Principles](#)”). RM is a vector quantity, having both direction, usually related to the direction of the Earth’s field at the time of origin, and intensity, related to both mineral phase and the external field. Descriptions of remanent magnetization, associated paleomagnetic techniques, and results are detailed in standard paleomagnetic textbooks such as Butler (1992), McElhinny and McFadden (2000), and Tauxe (2010). More detailed discussion of the theory and development of remanent magnetization can be found in rock magnetism books, including those by Nagata (1961), Stacey and Banerjee (1974), O’Reilly (1984), and Dunlop and Özdemir (1997).

Source of RM

Remanence is a property unique to a small group of minerals possessing ferromagnetic or antiferromagnetic properties, mostly iron oxides and iron sulfides. Remanence is observable in hysteresis behavior, when, after saturation, the applied field is reversed and decreased to zero. If the magnetization does not also return to zero, but retains a measurable quantity, a remanent magnetization is present (Fig. 1). This characteristic is temperature dependent, with only some of the mineral phases possessing remanence at earth surface temperatures.

The most common and important magnetic minerals on Earth belong to the cubic oxide series magnetite ($\text{Fe}^{2+}\text{Fe}_2^{3+}\text{O}_4$) – ulvöspinel ($\text{Fe}_2^{2+}\text{Ti}^{4+}\text{O}_4$), and the rhombohedral oxide series hematite ($\text{Fe}_2^{3+}\text{O}_3$) – ilmenite ($\text{Fe}^{2+}\text{Ti}^{4+}\text{O}_3$). Both series have important solid solution versus temperature relationships, as well as magnetic complexities of key interest in the rock magnetism. Additionally, both series show remanence properties that vary with composition. Furthermore, the oxide bulk compositions in the vicinity of equilibrium tie lines between ilmenite and magnetite are found in a majority of igneous and metamorphic rocks, especially basalts. In these

Remanent Magnetism, Fig. 1 Hysteresis loop of hematite-dominated sample of the El Laco deposit, northern Chile. Horizontal axis is the external field, in Tesla; vertical axis is relative magnetization. Mr indicates the remanent magnetization left after the sample is saturated and returned to a zero field

assemblages, the slopes of the tie lines are a function of temperature, whereas tie line positions are a function of the oxygen fugacity of equilibration according to the oxygen thermobarometer (Buddington and Lindsley 1964).

End-member hematite is antiferromagnetically ordered with equal and opposite magnetic moments in alternate cation layers. However, at room temperature, a weak ferromagnetic moment is produced because the alternate moments are $\sim 0.13^\circ$ away from being perfectly antiparallel (Dzialoshinskii 1957). This effect is commonly referred to as “spin-canting” and such hematite is termed “canted--antiferromagnetic.” Many oxidized sediments contain hematite, and carry this weak, but very stable magnetization, which is mainly due to its high coercivity.

The temperature and composition phase relations of the hematite-ilmenite series are a result of a complex interaction of Fe-Ti ordering and magnetic ordering at high temperature. Slow cooling to intermediate to low temperatures produces exsolution of discrete ilmenite and hematite (Burton 1991; Harrison et al. 2000; Ghiorso and Evans 2008). Exsolved grains contain two phases, a host (hematite or ilmenite) and lamellae of the second phase. Ilmeno-hematite (hematite with ilmenite exsolution), or hemo-ilmenite (ilmenite with hematite exsolution) commonly have a strong, and very stable magnetization, referred to as “lamellar magnetism.” Lamellar magnetism is due to a defect in the magnetic moment at the interface (or contact layer) between the two phases (Robinson et al. 2002, 2004) where a ferrimagnetic substructure is present because of the different quantity of Fe^{2+} and Fe^{3+} ions in contact Fe layers, as compared to standard Fe^{3+} layers in adjacent hematite.

Intermediate members of this series rapidly cooled from high temperature produce intermediate metastable phases that are ferrimagnetic and show complicated magnetic properties near and below room temperature (Ishikawa and Akimoto 1957; Burton et al. 2008; Robinson et al. 2010) with some compositions with varied Fe-Ti ordering showing magnetic self-reversal (Harrison et al. 2005; Ishikawa and Syono 1963).

Natural Remanent Magnetization (NRM)

The magnetization held by a rock sample prior to subjection to any laboratory procedures is referred to as Natural Remanent Magnetization (NRM). It is the sum total of all remanences held in the rock and may include primary as well as secondary remanences arising from different processes. The NRM is differentiated from induced magnetization, which a rock may acquire as it sits in an external field, and loses when the field is removed. Induced magnetization is dependent on the magnetic susceptibility of the material as well as the strength of the external field. NRM is traditionally described by the manner of acquisition of the remanences involved,

leading to a number of both natural and laboratory magnetizations, as described below.

Thermoremanent Magnetization (TRM)

Igneous rocks, cooling down from a molten state through the Curie or Néel temperature (T_c or T_n), obtain a thermoremanent magnetization (TRM) parallel to the ambient field. For magnetite this temperature is 580°C while for hematite it is 675°C . At these temperatures the spontaneous nature of the ferromagnetic material occurs and remanence is blocked just below this temperature. The material must cool slightly further to the blocking temperature (T_b) before this magnetization becomes locked in with a relaxation time equivalent to geologic time spans. The direction of remanence, so important to the whole field of paleomagnetism, becomes permanent at this point, with a net direction parallel to the ambient field. The intensity of the magnetization is influenced by the size of the external field, and by the phase, composition, and grain size of the ferromagnetic minerals present.

The TRM preserved in igneous rocks is a summation of the remanences of all the ferromagnetic grains present. This means there may be a range of Curie temperatures and related blocking temperatures, giving rise to partial thermal remanence (pTRM). As a simple case, if a rock had both pure hematite and pure magnetite grains present, the hematite grains would lock in the field slightly below 675°C while the magnetite grains would provide additional remanence once the rock cooled to below 580°C . Commonly, a combination of oxide minerals of varying composition provide for remanence acquired at a range of temperatures. In Fig. 2, a plot of pTRM is shown for a basalt with low Ti-magnetite. Metamorphic rocks heated to above their Curie temperatures will have the remanence reset as the material cools down. High grade metamorphic rocks, such as granulite- and amphibolite facies rocks, heated to above $600\text{--}700^\circ\text{C}$ will have all the existing magnetic minerals remagnetized in the external field at the time of cooling, whereas rocks of lower metamorphic grade will have only minerals with T_c below the peak metamorphic temperature completely reset. Néel (1955) introduced the theory of thermoremanence; Dunlop (1977) and Dunlop and Özdemir (1997) provide detailed treatment of the theory.

Detrital Remanent Magnetization (DRM)

Sedimentary rocks obtain a remanent magnetization in a very different way. Here the detrital grains settling in a water column are influenced by the external magnetic field producing a depositional remanent magnetization (DRM).) These grains are also influenced by procedures in the sedimentary

Remanent Magnetism, Fig. 2 Thermoremanent magnetization plot from a Tertiary basalt, Meseta Lago Buenos Aires, Argentina. Upper curve labeled TRM represents the amount of magnetization left after increasing heatings up to 600 °C, with nearly 75% of the remanence being removed between 550 °C and 600 °C. Lower curve (pTRM) indicates the percentage of TRM residing within certain blocking temperatures

environment imparting a post-depositional remanence (pDRM). The general term of detrital remanent magnetization includes both processes of depositional as well as post-depositional magnetization.

When eroded ferromagnetic grains enter the sedimentary regime, they retain their magnetic moments even though the original orientation of that moment is lost. These grains, as they settle through a water column, respond to the external field, and in a mechanical response, become aligned with the influencing field over a very short time period. As redeposition experiments in the laboratory have shown, this theory is not so simple as projected (Verosub 1977). There are a number of changes that can occur once the grain is deposited, but before magnetization is locked in. These effects lead to a pDRM, or post-depositional remanent magnetization, a prevalent but complicated process (Shcherbakov and Shcherbakova 1983). Common effects are the dewatering of the sediment, compaction of the grains, and bioturbation, all of which allow for ferromagnetic particles, particularly small ones, to realign. Magnetization is not considered final until the grains are no longer able to move about or realign, occurring at a depth referred to as the lock-in depth. This gives grain size an importance in DRM, with smaller grains more susceptible to realignment, but also yielding stronger and more stable remanence. To this end fine-grained sediments, as mudstones and siltstones, retain a remanence better than coarser-grained rocks such as sandstones or conglomerates.

The notion of individual grains settling in a water body has recently been investigated (Tauxe et al. 2006) and found to be more complicated. In marine environments in particular, fine-grained sediments do not sink as discrete particles, but rather flocculate with coexisting nonmagnetic particles. The entire floc needs to be aligned with the external field, leading to variations in remanence, especially with respect to intensity, from that predicted by theory and redeposition experiments.

Chemical Remanent Magnetization (CRM)

Commonly rocks undergo chemical changes after formation, usually at temperatures below the Curie temperature of the minerals involved. These changes can be alterations to existing magnetic minerals and/or the creation of new iron oxides within the rock unit. These changes can result in new or altered remanences; this process is commonly referred to chemical remanent magnetization (CRM).

A classic example of CRM is “red beds” or sedimentary rocks with strong reddish hues due to the ubiquitous presence of hematite. Such rocks may have a DRM from the time of formation, due to the presence of detrital grains of magnetite and/or hematite. After deposition, changes brought on by differing environments, a range of aqueous solutions, or variations in oxidation state may result in weathering of existing ferromagnetic minerals, or in the deposition by precipitation of new ferromagnetic minerals. Existing magnetic minerals may break down to weaker or nonmagnetic minerals, such as hematite altering to goethite or pyrrhotite to pyrite. Ferromagnetic minerals may also alter to other magnetic minerals with different remanence characteristics. One example is the oxidation of magnetite to maghemite. Another alteration common is that of nonmagnetic grains to magnetic ones, such as the case of Fe-bearing silicate grains altering to discrete hematite grains. New ferromagnetic minerals develop, such as the formation of hematite cements and coatings, which is pervasive in red beds develops.

CRM can also be produced during progressive metamorphism, for example, when Fe-silicates breakdown to produce magnetite, in hematite-ilmenite solid solutions, or when Fe-bearing silicates react with pyrite (nonmagnetic FeS₂) to produce pyrrhotite (magnetic FeS). Lamellar magnetism mentioned earlier is a CRM because it is produced during the chemical reaction of exsolution and not at the Curie temperature of the minerals; with slow cooling this can occur hundreds of degrees below the T_c.

CRM is also recognized in igneous rocks, such as in the formation of secondary hematite in cracks and fractures in basalts or around the rims of discrete magnetite grains. In this case, the CRM is often hard to distinguish from the original TRM, as the CRM is quite stable and many of the magnetic properties of the two remanences are similar.

Viscous Remanent Magnetization (VRM)

At room temperature, in low ambient fields, rocks may acquire a component of magnetization in the direction of the “present” field. This remanence acquired over long time periods in low fields, such as the Earth’s field, is referred to as viscous remanent magnetization (VRM). It is generally assumed that the strength of the VRM is related to the log of the time involved, although this is a gross simplification of the situation. The importance of other factors, including grain size, initial magnetic state, and the angle of the ambient field relative to the original remanence vector have recently been investigated and shown to also affect the strength of VRM) (Yu and Tauxe 2006). Although VRM is ubiquitous in geologic examples and is found associated with many different rocks types, in many cases it is small and can easily be removed by demagnetization techniques. Due to its soft nature, VRM is often referred to as an “overprint” commonly representing the present magnetic field and must be removed prior to investigating the primary remanence.

In natural situations where temperatures may be elevated for a considerable time, as in low-grade metamorphism, or in young oceanic lithosphere, there is commonly a thermal viscous remanent magnetization (TVRM) acquired. Here, increased temperature over extended time periods enhance the viscous remanence and produce a magnetization that may eventually replace the original NRM. Pullaiah et al. (1975) have investigated such magnetization changes over a range of temperatures and timescales, with additional discussion provided by Dunlop and Özdemir (1997).

Isothermal Remanent Magnetization (IRM)

The presence of a large magnetic field over a short time period may also produce a remanent magnetization, referred to as isothermal remanent magnetization (IRM). An IRM can be imparted in the laboratory and used to help identify properties of magnetic materials. Samples are subjected to increasingly large external fields, usually to 1 T or larger, and the resulting magnetization recorded. Differences in composition, concentration, grain size, and saturation state effect the acquisition of IRM. For example, magnetite-bearing samples will saturate in fields of 0.1–0.3 mT, while hematite-dominated rocks will require fields larger than 1 T to reach saturation (Fig. 3).

In the natural environment, a typically cited example of an IRM is the magnetization gained in a rock after being struck by lightning. The large magnetization produced by the electric currents in lightning imparts an intense, but chaotic remanence on surface rocks. First studied by Cox (1961), IRM is common in regions subject to intense thunderstorms, such as the desert southwest of the North America. In some cases, the effect of the IRM can be removed by demagnetization; in

Remanent Magnetism, Fig. 3 Normalized IRM acquisition in fields up to 1 T; closed symbols are Jurassic diabase dikes with magnetite; open circles are Jurassic mudstones with hematite

other samples, the magnetization has been totally reset, giving rise to paleo-magnetic sites with random directions (Tauxe et al. 2003).

However, this type of IRM is commonly accompanied by high heat; therefore, the term is slightly misused.

Applications of Remanent Magnetization

RM is used extensively in the disciplines of magnetism, including paleomagnetism, rock magnetism, and the study of magnetic anomalies. The study of paleomagnetism centers on the identification and description of the remanent field held in rocks. Results from the measurement of RM are used widely in the study of plate tectonics, structure, regional tectonics, stratigraphy, volcanology, and archeology. Positions of the earth’s magnetic field at specific times in the geologic past provide us invaluable information on the position of continental bodies in the past, the interrelationship between different continents, and the paths they have followed in subsequent motions across the earth’s surface. RM can provide age information by comparison to established reversal timescales, as well as relative ages within a region. Regional tectonics, local rotations, and timing of folding can all be investigated using the remanence recorded in suitable rock units. Stratigraphic studies, especially in the wealth of deep-sea sediment cores from international drilling projects, lake sediments, or in thick sedimentary sequences on

(Redrawn from McEnroe et al. 2001)

land, can be established and compared using the recorded remanence.

Experimental studies in rock magnetism make excellent use of the remanent magnetization properties of rocks and minerals. Studies of hysteresis behavior, magnetization at high and low temperatures, and responses to acquisition and removal of laboratory remanences all provide important information on oxide composition, grain size, and magnetic properties of a wide range of natural and synthetic materials.

Remanent magnetism plays an important part in the interpretation of magnetic anomalies. Well established in the 1960s is the study of marine magnetic anomalies from the seafloor, remanent polarity of extruded basalts played a pivotal role in the interpretation of observed anomalies (Vine and Matthews 1963; Heirtzler et al. 1968). The use of the polarity sequence preserved in the ocean crust allows for dating of the seafloor as well as calculations of spreading rates and investigations of plate histories. Anomalies on land show considerable complexities and many are assumed to be entirely related to induced fields due to the present magnetic field.

But, in many cases, there is a significant component of remanent magnetization interacting with the induced field, and depending on the remanent direction and intensity, enhancing or at times annihilating the induced field (McEnroe et al. 2009). An excellent case of remanent magnetization producing strong aeromagnetic anomalies comes from the Rogaland Igneous Complex in southern Norway (McEnroe et al. 2008), where anorthosites and a layered intrusion have intense remanence roughly antiparallel to the present field, producing large negative anomalies (Fig. 4).

Exploration for natural resources by aeromagnetic surveys has been widely used since the 1950s. The classic work by Balsley and Buddington (1958) and later by McEnroe and Brown (2000) in the oxide rich area of the Adirondack Mountains of New York required a detailed knowledge of the RM for accurate interpretation of the data. Understanding the contribution of RM to magnetic anomalies will be crucial for future exploration as the accuracy and resolution of these surveys increase. Magnetic surveys will also be at the forefront for geological mapping of Earth and other planets.

Summary

Remanent magnetization is a permanent magnetization residing in earth materials that is gained when the material is formed or altered in the presence of the Earth's magnetic field. Measurable RM is found in most rocks, ranging from metamorphic gneisses to lava flows to marine and lake sediments. The remanence is carried by iron oxides and sulfides, but magnetite and hematite are by far the most common and the most important remanence carriers. RM is categorized and described by various methods of acquisition; TRM for remanence produced as minerals cool through their Curie temperatures, DRM for the remanence obtained as detrital grains of magnetic minerals align during the deposition process, and CRM for the process where remanence develops from chemical changes in the rock. RM forms the basis for research in paleomagnetism, where the direction, intensity, and age of the remanence are determined and interpreted. It is also useful in experimental studies of rock magnetism, and in the investigation of anomalies in global, regional, and local magnetic field measurements.

Remote sensing data; Space imagery

Definition

Remote sensing	Refers to small- or large-scale acquisition of information of an object or phenomenon (e.g., earth surface features), by the use of either recording or real-time sensing device (s) such as by way of aircraft, spacecraft, satellite, buoy, or ship that are not in physical contact with the object.
Geographic information system	Refers to spatial data management and analysis tools that can assist users in organizing, storing, editing, analyzing, and displaying positional and attribute information about geographical data.
Lineaments	Any linear features that can be picked out as lines (appearing as such or evident because of contrasts in terrain or ground cover, tone, pattern, size, etc.) in aerial or space imagery.
Tectonics	A field of study within geology concerned generally with the structures within the lithosphere of the Earth (or other planets) and particularly with the forces and movements that have operated in a region to create these structures.

Neotectonics	A subdiscipline of tectonics which deals with the current or recent geologic deformations.
Active fault	A planar fracture in rocks with visible displacement or seismic activity that has occurred during the geologically recent period, as opposed to passive faults that show no movements since their formation.
Lithology	The scientific study and description of rocks/rock types in terms of compositional and physical character of the rock.
Geomorphic features	Landform features such as rivers and peneplains formed by geomorphic processes (e.g., erosion and mass-wasting) that shape them.
Strain meter	An instrument used by geophysicists to measure the deformation of the Earth in the field.

Introduction

Mapping of lineaments from various space imagery are a commonly used initial step in tectonic studies. The surface expression of geological structures such as faults, joints, dykes, veins, and straight routes of rivers are often displayed or represented in the form of lineaments in aerial photographs or on remotely sensed images. In addition, remote sensing data are useful for detecting lithology and geomorphic features, which are, in turn, important in assessing the mechanisms of faulting. The most common and widely used remote sensing techniques include: Satellite Pour l’Observation de la Terre (SPOT), which is a high-resolution optical imaging Earth Observation Satellite (EOS), Landsat satellite both multispectral scanner (MSS), and thematic mapper (TM) including enhanced thematic mapper (ETM), Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Shuttle Radar Topographic Mission (SRTM) and/or *SAR Interferometry* (InSAR), and Global Positioning System (GPS). Data acquired from optical, thermal, radar images or digital terrain elevation at the same or different sensor platforms or devices are all useful for tectonic studies.

Lineament mapping and analysis is a combined effort of technology and field evidence (Fig. 1). The availability of multispectral and multi-sensor data with synoptic coverage and use of different image enhancement techniques provides an opportunity to prepare more reliable and comprehensive lineament maps useful for tectonic studies. Field studies or ground truthing of orientation measurements of structural features and identifying rock types provide support for verifying remote sensing derived tectonic interpretation. Geographic information system (GIS) facilitates integration

Remote Sensing and GIS Techniques for Tectonic Studies, Fig. 1 A simplified flow chart showing the methodology of tectonic study using remote sensing and field data in a GIS framework

of all data types and provides a strong basis for tectonic interpretation of structural features.

Data and Method

Mapping of geological structures from various space imageries is a commonly used initial step in tectonic studies. The routine procedure for extracting tectonic features from digital remote sensing data usually involves initial digital image enhancement followed by manual interpretation (Suzen and Toprak 1998). There have been significant approaches for the evaluation and automatic detection of lineaments and curvilinear features from satellite images (Karnieli et al. 1996). However, the human expert judgment still remains to be an asset for lineament detection and interpretation.

Satellite-based remote sensing data may be optical image (e.g., SPOT and Landsat), which usually senses the behavior of visible, ultraviolet, and infrared light components of the electromagnetic energy used in imaging. The data could also be thermal image in which the devices sense the thermal energy of the electromagnetic spectrum. The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) is an example of modern remote sensing device that senses the behavior of visible, ultraviolet, infrared light, and thermal infrared components of the electromagnetic energy spectrum. The remote sensing satellite may also acquire radar images such as the Shuttle Radar Topographic Mission (SRTM) and/or Interferometric Synthetic Aperture Radar (InSAR) in which the system has a transmitter that

emits microwaves or radio waves of the electromagnetic energy to detect objects. The Global Positioning System (GPS) is a US space-based global navigation satellite system. GPS is made up of three parts: satellites orbiting the Earth; controlling and monitoring stations on Earth; and the GPS receiver that reads broadcasted signals from space sent by GPS satellites. Each GPS receiver then provides three-dimensional location based on latitude, longitude, and altitude, and the time that are useful for tectonic studies.

Digital elevation models (DEM) may be prepared in a number of ways, but they are frequently obtained by remote sensing rather than by direct survey. One powerful technique for generating digital elevation models is InSAR: two passes of a radar satellite (such as RADARSAT-1 or TerraSAR-X), or a single pass if the satellite is equipped with two antennas (like the SRTM instrumentation), suffice to generate a digital elevation map with extensive areal coverage and high resolution (10–30 m). Alternatively, other kinds of stereoscopic pairs can be employed using routine photogrammetric techniques, where two optical images acquired with different angles taken from the same pass of an airplane or an EOS such as the high-resolution stereo of SPOT5 or the visible and near-infrared band of ASTER (e.g., Hirano et al. 2003).

Remote Sensing

The surface expression of lineaments displayed in aerial photographs or remote sensing data (Fig. 2) may be passive faults, showing no movements since their formation or may be active faults with movements created by either earthquakes or ongoing uplifting. Earthquakes and uplifts are related to tectonic movements in the subsurface. The surface expression of these movements as structures visible on satellite imageries can be mapped and used to investigate the tectonic movements. Time series thermal satellite remote sensing datasets were used to detect pressure buildup due to tectonic activities and associated subsurface degassing that created changes in the thermal regime prior to an earthquake event (Saraf and Choudhury 2005). Such studies are useful in locating earthquakes' epicenters and understanding the fault mechanics involved in the deformation during earthquake occurrences and uplifting processes.

DEM acquired from satellites such as SRTM data or optical images are useful for derivation of topographic parameters such as slope and surface curvatures (geomorphic indices) for mapping drainage networks and lineament extraction (Zizioli 2008; Demirkesen 2008). These morphotectonic parameters can be used as indicators of active tectonics in a region. For instance, rivers are sensitive to changes in tectonic deformation, adjusting their routes over different periods of time depending on the physical properties of the host rocks, climatic effects, and tectonic

Remote Sensing and GIS Techniques for Tectonic Studies, Fig. 2 Different types of remote sensing data showing conspicuous NE-SW trending lineaments from 12 km $\times$ 12 km area (a) SPOT band

3, (b) digitized enhanced Landsat TM band 5, and (c) minimum curvature image derived from SRTM digital elevation model. The lineaments represent both extensional and strike-slip tectonics

activity. Thus, the drainage system of a region records the evolution of tectonic deformation. Quantitative measurements of a number of geomorphic indices are commonly used as a reconnaissance tool in tectonic geomorphology studies to identify areas experiencing tectonic deformation. Combinations of different geomorphic indices derived from DEM data allow the quantification of surface deformation both on maps and on stream profiles. It is possible to assess and quantify the rate of uplift by studying the influence of faults on stream geometry and changes in direction as a result of neo-tectonic activity (Gloaguen et al. 2008). Such thematic geomorphic indices can easily be incorporated into a GIS tool for further analysis and interpretation.

Interferometric Synthetic Aperture Radar (InSAR) is a radar technique used in geodesy and remote sensing. This geodetic method measures the line-of-sight displacements and uses two or more synthetic aperture radar (SAR) images to generate maps of surface deformation or digital elevation, using differences in the phase of the waves returning to the satellite, or aircraft. The technique can potentially measure millimeter-scale or even lower changes in deformation over time spans of days to years. InSAR can be used to measure ground movements due to earthquakes and to monitor creep and strain accumulation on faults (e.g., Stramondo et al. 2005). Due to its easy integration within a GIS environment, DEM data is important in such analyses. Time series data, a sequence of space imagery shots taken at different times, is a requirement in such studies. Then the changes are detected at observation points that have a fixed geographical location for later comparison and monitoring purposes.

GPS measurements, among other applications, are now in use to determine the motion of the Earth's tectonic plates and deformation around active faults and volcanoes. It provides a powerful means to directly measure the kinematic pattern of present-day crustal deformation by setting up several regional
